

Posttranskriptionelle Regulation des Retrotransposons TRE5-A in *Dictyostelium discoideum*

**Dissertation
zur Erlangung des akademischen Grades
„doctor rerum naturalium“ (Dr. rer. nat.)**

vorgelegt dem Rat der Biologisch-Pharmazeutischen Fakultät
der Friedrich-Schiller- Universität Jena

von Diplom-Biologin Anika Schmith
geboren am 20. März 1983 in Eisenhüttenstadt

1. Gutachter: Prof. Dr. Thomas Winckler, Friedrich-Schiller-Universität Jena
2. Gutachter: Prof. Dr. Hans-Peter Saluz, Friedrich-Schiller-Universität Jena
3. Gutachter: Prof. Dr. Rupert Mutzel, Freie Universität Berlin

Tag der Disputation: 26.05.2016

1. Zusammenfassung

TRE5-A und DIRS-1 sind Retrotransposons aus dem eukaryotischen haploiden Organismus *Dictyostelium discoideum*. Von beiden existieren sowohl *Sense*- als auch *Antisense*-Transkripte. Dies führte zur Vermutung einer posttranskriptionellen Regulation beider Retrotransposons durch zelleigene RNA-Interferenz-Prozesse. Für DIRS-1 konnte in dieser Arbeit gezeigt werden, dass die RNA-abhängige RNA-Polymerase RrpC als Komponente des RNAi-Systems in *D. discoideum* für die posttranskriptionelle Regulation von DIRS-1 benötigt wird. RrpC verhindert dabei die Transkriptakkumulation von DIRS-1 und somit dessen Retrotransposition. Ebenfalls ist RrpC für die Synthese der DIRS-1 siRNAs notwendig, da im entsprechenden *rrpC-Knockout*-Stamm eine signifikante Reduzierung der siRNAs von DIRS-1 beobachtet werden konnte.

Frühere Arbeiten konnten den Wirtsfaktor C-Modul-bindender Faktor A (CbfA) aus *D. discoideum* als Transkriptionsregulator identifizieren, der *in vitro* an das C-Modul von TRE5-A bindet. In dieser Arbeit konnte gezeigt werden, dass eine reduzierte Expression von CbfA im Stamm JH.D, mit einer CbfA-Expression von nur noch 5 %, zu einem drastischen Abfall der TRE5-A-Transkriptmenge und -Retrotransposition im Vergleich zum Wildtyp führt. Die reduzierte Transkriptmenge betrifft dabei sowohl die *Sense*- als auch die *Antisense*-Transkripte von TRE5-A, wobei eine direkte Bindung von CbfA an die entsprechenden Promotorregionen von TRE5-A ausgeschlossen werden konnte. Den verschiedenen Domänen von CbfA scheinen dabei unterschiedliche Aufgaben zuteilzuwerden, da die C-terminale Domäne (CTD) von CbfA die Transkriptakkumulation, aber nicht die Retrotranspositionsfrequenz von TRE5-A beeinflussen kann.

Die in dieser Arbeit mit Wildtyp und JH.D durchgeführten vergleichenden RNA-Seq-Experimente zur weiteren Funktionsaufklärung von CbfA zeigten eine Überexpression der Argonaut-Proteine AgnC und AgnE in der CbfA-Mutante. Dies bestätigte die bereits vorhandene Vermutung, dass RNAi-Prozesse an der TRE5-A-Regulation beteiligt sein könnten. Zur Verfügung stehende *agnC*⁻ und *agnE*-Stämme zeigten eine TRE5-A-Überexpression, was auf eine direkte Funktion der beiden Argonaut-Proteine in der TRE5-A-Regulation schließen lässt. Um *agnC* beziehungsweise *agnE* im CbfA-Wildtyp-Hintergrund überexprimieren zu können, wurden Genaktivierungsmutanten (GA) von AgnC und AgnE erzeugt. Diese Stämme wurden auf ihren Einfluss auf die TRE5-A-Expression und -Retrotransposition hin charakterisiert. Die Überexpression von *agnC* oder *agnE* führte zu einem Abfall der TRE5-A-Transkriptmenge und der GA-AgnC-Stamm zeigte eine signifikante Reduktion der Retrotranspositionsfrequenz von TRE5-A. Dies lässt auf eine

posttranskriptionelle Regulation von TRE5-A schließen. CbfA jedoch scheint diese Regulation zu supprimieren, wodurch die TRE5-A-Retrotranspositionsaktivität im Genom erhalten bleibt. Dies wiederum könnte positive Effekte auf die Genomevolution von *D. discoideum* haben.

Die in dieser Arbeit durchgeführten phylogenetischen Analysen von CbfA innerhalb und außerhalb der sozialen Amöben ermöglichten die Darstellung einer neuen Proteinfamilie: Die CbfA-ähnlichen Proteine. Dabei konnte gezeigt werden, dass die Jumonji/Zinkfinger-Region (Jmj/ZF) am N-Terminus von CbfA eine konservierte Domäne ist, die womöglich an Chromatin-Modifikationsprozessen beteiligt ist. Zwischen verschiedenen Organismen ist die CTD sehr variabel. Dies deutet auf eine schnelle evolutionäre Entwicklung dieser Domäne als Ausdruck einer artspezifischen Anpassung hin. Die CbfA-Proteine der *Dictyosteliidae*, zu denen auch *D. discoideum* gehört, zeigen dagegen eine hohe Konservierung der CTD. Die CTD von *Polysphondylium pallidum*, eine mit *D. discoideum* entfernt verwandte Art, konnte in Genexpressionsstudien viele der von der *D. discoideum*-CTD beeinflussten Gene ebenfalls regulieren.

2. Summary

TRE5-A and DIRS-1 are retrotransposons of the eukaryotic haploid organism *Dictyostelium discoideum*. Both elements produce sense and antisense transcripts and may therefore be regulated posttranscriptional by RNA interference (RNAi). In this work it was shown that the RNA-dependent RNA polymerase RrpC of *D. discoideum* is required for the posttranscriptional regulation of DIRS-1. RrpC prevents the accumulation of DIRS-1 transcripts and consequently its retrotransposition. RrpC is also required for the synthesis of DIRS-1 siRNAs because a significant reduction of siRNAs of DIRS-1 had been observed in the corresponding *rrpC*-knockout.

Previous work identified the C-module-binding factor A (CbfA) as a general regulator of transcription that binds to the C-module of TRE5-A in vitro. In this work it was shown that a reduced expression of CbfA in the mutant JH.D leads to a drastic reduction of sense and antisense transcripts and the frequency of TRE5-A retrotransposition in comparison to wild-type cells. Direct effects of CbfA to the corresponding promoter regions of TRE5-A could be excluded using reporter gene assays, assuming an indirect regulatory role of CbfA. The different domains of CbfA seem to have different functions in the regulation of TRE5-A, because the C-terminal domain of CbfA can influence the accumulation of TRE5-A transcripts but not the frequency of retrotransposition.

In this work comparative gene expression studies were performed in wild-type and JH.D cells to evaluate CbfA's gene regulatory functions. In these experiments an overexpression of Argonaute proteins AgnC and AgnE in the CbfA mutant was observed. This confirmed the assumption that RNAi-mediated processes are involved in the regulation of TRE5-A. Knock-out *agnC*⁻ and *agnE*⁻ strains were shown to overexpress TRE5-A, whereas gene activation mutants overexpressing *agnC* and *agnE* showed suppression of both TRE5-A expression and retrotransposition. This indicates a posttranscriptional regulation of TRE5-A. CbfA seems to repress a RNAi pathway involving AgnC and AgnE, thereby supporting the amplification of TRE5-A in the *D. discoideum* population. The continuous replication of TRE5-A may have a profound impact on the genome evolution of *D. discoideum*.

Phylogenetic analyses uncovered a new family of proteins named "CbfA-like proteins". Members of this family are widespread in dictyostelids (comprising CbfA and CbfB) and filamentous fungi and contain a "carboxy-terminal jumonji" (JmjC) domain connected to two characteristic zinc finger-like motifs that together may constitute a chromatin-modifying entity. Among different dictyostelid species the carboxy-terminal domain (CTD) is highly variable despite a highly conserved "core" that exists only in CbfA proteins. Whereas the CbfA-CTDs

are conserved enough to allow *Polysphondylium pallidum* CbfA-CTD to fully adopt the functions of the *D. discoideum* ortholog, the rapid evolution of CTDs in dictyostelid CbfB proteins and fungal CbfA-like proteins may reflect a rapid evolutionary development required for species-specific adaptation.

3. Einleitung

3.1 Der Organismus *Dictyostelium discoideum*

Dictyostelium discoideum wurde Anfang des 20. Jahrhunderts in den Wäldern North Carolinas entdeckt und als Isolat NC4 bezeichnet (Raper, 1935). Er gehört phylogenetisch zur Klasse der *Dictyosteliidae* (Schilde und Schaap, 2013). Diese zählen zur Gruppe der *Amoebozoa* und sind mit den Tieren und Pilzen näher verwandt als den Pflanzen (Eichinger et al., 2005). Die *Amoebozoa* sind in verschiedene Gruppen unterteilt, die eine lange unabhängige evolutionäre Entwicklung von mehreren hundert Millionen Jahren aufweisen (Tekle et al., 2008). Die Analyse eines Sets von 30 orthologen Genen aller vorhandenen *Amoebozoa*-Genome führte zu der in Abbildung 1 dargestellten Topologie. Die *Myxogastria*, mit *Physarum polycephalum* als Vertreter, und die *Dictyosteliidae* bilden dabei Schwestergruppen (Glöckner und Noegel, 2013). Die Analysen von Glöckner und Noegel (2013) konnten zeigen, dass nur einige wenige hundert *Amoebozoa*-spezifische Gene existieren. Das „Kerngenom“ des letzten gemeinsamen Vorfahren aller Eukaryoten bedarf demnach nur geringfügigen Ergänzungen, um die Gruppe der *Amoebozoa* zu etablieren. Die verschiedenen Lebensstile und Lebenszyklen mit den entsprechenden Spezifikationen führten vermutlich zu den genetischen Änderungen, die zur Entstehung der verschiedenen Linien innerhalb der *Amoebozoa* führte (Glöckner und Noegel, 2013).

Abb. 1: Phylogenie der *Amoebozoa*. Stammbaum wurde erstellt mit Hilfe von *neighbour-joining* anhand eines Gensets von 30 Orthologen der vorhandenen *Amoebozoa*-Genome. Für die Wurzel wurde nach humanen Orthologen gesucht. A.: *Acanthamoeba*; D.: *Dictyostelium*; mya: Millionen Jahre; *P. pallidum*: *Polysphondylium*; *P. polycephalum*: *Physarum*. (Glöckner und Noegel, 2013).

Die Linie der *Dictyosteliidae* etablierte sich vor ca. 600 Millionen Jahren. Sie stellen aufgrund ihres Lebenszyklus mit Ausbildung eines multizellulären Stadiums den Übergang vom Einzeller zum Vielzeller dar. Es existieren etwa 150 *Dictyosteliidae*-Arten, die in ein phylogenetisches System eingeordnet sind (Romeralo et al., 2011). Diese können den Gattungen *Dictyostelium*, *Polysphondylium* und *Acytostelium* zugeordnet werden (Alvarez-Curto et al., 2005; Schaap et al., 2006). Zunächst erfolgte die Einteilung anhand morphologischer Charakteristika. Neuere molekulare phylogenetische Analysen der Sequenzen der kleinen Untereinheit der ribosomalen rRNA und der Vergleich von α -Tubulin führten zu der Einteilung in vier Gruppen, namentlich Gruppe 1 bis 4, in welche die verschiedenen Arten von *Dictyostelium*, *Polysphondylium* und *Acytostelium* eingruppiert sind (Schaap et al., 2006). Genanalysen konnten zeigen, dass orthologe Gensets innerhalb der Arten zum großen Teil aus Elementen der allgemeinen Zellmaschinerie wie Transkription, Translation und Primärmetabolismus bestehen. Es konnten keine Art-spezifischen Genfamilien identifiziert werden, aber durchaus Art-spezifische Erweiterungen einiger Genfamilien (Glöckner und Noegel, 2013). Dabei handelt es sich meist um Funktionen, welche die interzelluläre Kommunikation betreffen (Heidel et al., 2011). Der Entwicklungszyklus der *Dictyosteliidae* scheint bereits vor circa 600 Millionen Jahren etabliert worden zu sein, da viele Gene des Entwicklungszyklus konserviert sind, was sowohl Genstruktur als auch Transkriptionsprofil betrifft (Parikh et al., 2010; Glöckner und Noegel, 2013). *D. discoideum* gehört zu den am besten erforschten Arten der *Dictyosteliidae*. Er weist eine kurze Generationszeit auf und ist unter Laborbedingungen einfach zu kultivieren. Dies und sein besonderer Lebenszyklus mit dem Wechsel vom Einzeller zu einem multizellulären Organismus machten *D. discoideum* zu einem interessanten Modellorganismus für die Erforschung von z.B. Phagozytose, Chemotaxis, Zellmigration und Signaltransduktion.

Im einzelligen Stadium ernährt sich *D. discoideum* durch Phagozytose von Bakterien. Sobald die Futterquellen versiegen, wird von den Zellen pulsartig zyklisches Adenosinmonophosphat (cAMP) sezerniert. Benachbarte Zellen reagieren, indem sie auf die Stelle der höchsten cAMP-Konzentration zuwandern und ihrerseits cAMP sezernieren, wodurch auch weiter entfernte Zellen erreicht werden (Schaap, 2011). Auf diese Weise schließen sich etwa 100.000 Zellen zu einem multizellulären Aggregat zusammen (Abbildung 2). Als Pseudoplasmodium bewegen sich die Zellen, gelenkt durch Licht und Wärme, zu einem optimalen Standort und beginnen mit der Ausbildung des Fruchtkörpers (Schaap, 2011). Dieser besteht aus vakuolisierten toten Stielzellen und einem Sporenkopf mit Sporenzellen (Bonner und Lamont, 2005). Der in dieser Arbeit verwendete Stamm AX2 konnte aus dem Isolat NC4 selektioniert werden. Er kann sowohl auf Bakterien als auch

axenisch, durch Pinozytose in bakterienfreiem Flüssigmedium, kultiviert werden (Watts und Ashworth, 1970).

Abb. 2: Schematische Darstellung des Lebenszyklus von *Dictyostelium discoideum*. Unter günstigen Bedingungen auskeimende Sporen ernähren sich durch Phagozytose von Bakterien und vermehren sich durch Zellteilung (Wachstum). Sobald die Nahrungsquellen aufgebraucht sind, wird cAMP sezerniert, welches die Zellen zum Zentrum der höchsten cAMP-Konzentration lenkt (Aggregation). Zum Erreichen des Aggregationszentrums orientieren sich die Zellen aneinander (Strömen). Das Aggregat bildet eine schleimige Oberflächenhülle und lässt sich in Präsporen und Prästielzellen einteilen (*mound*). Der Zellkomplex wandert über das Substrat, um einen besseren Standort zu erreichen (*slug*). Ausgehend von der als *mexican hat* bezeichneten Struktur bildet sich dann der Fruchtkörper (Kulmination). Dabei schieben die schließlich absterbenden Prästielzellen die Präsporenzellen an die Stielspitze. Diese differenzieren zu Sporen aus, die von Zellulose und Glykoproteinen umhüllt sind und mehrere Jahre überdauern können. (modifiziert nach Gaudet et al., 2008).

D. discoideum hat ein haploides, 34 Mb großes Genom, das in sechs Chromosomen aufgeteilt ist. Die Chromosomen sind zwischen 4 und 9 Mb groß. *D. discoideum*-Zellen besitzen keine normalen Telomersequenzen. Stattdessen werden die Chromosomenenden von Bruchstücken des extrachromosomalen DNA-Elements gebildet, welches die ribosomalen rRNA-Gene trägt (Eichinger et al., 2005). Das vollständige 88 kb große extrachromosomale rDNA-Palindrom liegt in ungefähr 100 Kopien im Zellkern vor (Sucgang et al., 2003; Eichinger et al., 2005). Jedes Chromosom trägt an einem Ende eine Ansammlung des Retroelements DIRS (*Dictyostelium intermediate repeat sequence*), die vermutlich die Zentromere der Chromosomen bilden (Capello et al., 1984, 1985; Loomis et

al., 1995; Eichinger et al., 2005). Das Genom von *D. discoideum* weist mit 77,6 % einen hohen Gehalt an den Basen Adenin und Thymin auf. Auch besitzt das Genom eine hohe Gendichte. So findet sich statistisch alle 2,5 kb ein neues Gen. Es existieren ca. 12.500 Protein-kodierende Gene, die maximal ein bis zwei, im Mittel 129 bp große, Introns besitzen. (Eichinger et al., 2005; dictyBase). Im *D.-discoideum*-Genom finden sich 418 tRNA-Gene, von denen etwa 20 % in Paaren oder Triplets mit identischen Antikodons vorkommen (Eichinger et al., 2005; dictyBase). Es existieren außerdem ungefähr 70 weitere nicht-kodierende RNA-Gene (Aspegren et al., 2004; Hinas et al., 2006). Transposable Elemente stellen einen Anteil von ca. 10 % des Gesamtgenoms (Glöckner et al., 2001, 2002). Sie integrieren in Ansammlungen gleicher Elemente beziehungsweise im Fall der Non-LTR (*long terminal repeat*)-Retrotransposons in die Nähe von tRNA-Genen (Eichinger et al., 2005). Das haploide Genom von *D. discoideum* ist seit 2005 komplett sequenziert (Eichinger et al., 2005).

3.2 Transposable Elemente – Ein Überblick

Als Transposons oder transposable Elemente bezeichnet man DNA-Sequenzen, die befähigt sind, innerhalb des Genoms an neuen Positionen zu integrieren. Barbara McClintock hat diese „springenden Gene“ erstmals in Mais entdeckt (McClintock, 1948, 1950). Sie finden sich nahezu in allen eukaryotischen und prokaryotischen Genomen (Zaratiegiu, 2013). Ihr genomischer Anteil beträgt 3 – 20 % in Pilzen, 3 – 45 % in Tieren, 1 – 10 % in Bakterien und in Pflanzen sogar bis zu 90 % (SanMiguel et al., 1996; Mahillon und Chandler, 1998; Daboussi und Capy, 2003; Hua-Van et al., 2005; Filee et al., 2007). Transposable Elemente verbreiten sich von einer Zelle zur anderen im Wesentlichen über horizontalen Transfer und sexuelle Vererbung (Hickey, 1992; Kidwell, 1992). Aufgrund ihrer Häufigkeit und der Fähigkeit, sich im Genom frei zu bewegen, bewirken sie eine allgemeine Instabilität des Genoms (Ayarpadikannan und Kim, 2014). Ihre Insertionen können verschiedenste Effekte auf das Wirtsgenom ausüben. So können sie die Genexpression regulieren, die Rekombinationsrate erhöhen und ungleiche Cross-over hervorrufen (Ayarpadikannan und Kim, 2014). Auch können sie neue regulatorische Sequenzen schaffen, zu epigenetischen Veränderungen führen und das RNA-Editing beeinflussen (Belancio et al., 2009; Cordaux und Batzer, 2009).

Transposons werden anhand ihrer Zwischenprodukte klassifiziert: Klasse-I-Transposons, die Retrotransposons, replizieren über ein RNA-Zwischenprodukt (Finnegan, 1989). Dieses wird revers in eine DNA-Sequenz transkribiert und an einer neuen Position ins Genom integriert

(Pace und Feschotte, 2007). Klasse-II-Transposons, die DNA-Transposons, amplifizieren sich über ein DNA-Zwischenprodukt (Finnegan, 1989). DNA-Transposons besitzen endständige invertierte Sequenzwiederholungen und kodieren für eine Transposase. Diese schneidet das Element bei oder in der Nähe der Sequenzwiederholung aus dem Genom heraus und fügt es an anderer Stelle wieder ein („*cut-and-paste*“, Abbildung 3). Durch den versetzten Doppelstrangbruch entstehen kurze Sequenzverdopplungen (Finnegan, 1989; Levin und Moran, 2011). Eine Vermehrung dieser Transposons kann während der Zellteilung stattfinden, wenn die Transposition von einer Schwesterchromatide auf die andere erfolgt. Einige DNA-Transposons nutzen den Mechanismus der replikativen Transposition. Dabei verbleibt das Element an der Originalposition während eine erstellte Kopie an anderer Stelle ins Genom integriert wird (Shapiro, 1979; Johnson und Reznikoff, 1983; Parks et al., 2009; Kim, 2014). Retrotransposons verbreiten sich über einen Mechanismus, bei dem zunächst über eine *messenger*-RNA (mRNA)-Zwischenstufe eine Kopie des Elements erstellt wird, die dann an anderer Position im Genom eingefügt wird („*copy-and-paste*“) (Finnegan, 1989). Sie integrieren mit Hilfe der Integrase. Diese enthält in ihrer katalytischen Domäne das DDE-Motiv (D: Asparaginsäure, E: Glutaminsäure), welches sich auch in den Transposasen der DNA-Transposons findet und den kurzzeitigen Doppelstrangbruch ausführt (Polard und Chandler, 1995; Capy et al., 1996). Transposons unterteilen sich in autonome und nicht-autonome Elemente. Autonome Retrotransposons kodieren für die zur Reversen Transkription und Integration nötigen Proteine. Nicht-autonomen Retrotransposons fehlt mindestens eines dieser Proteine. Sie nutzen wiederum die Proteine der autonomen Elemente zur Mobilisierung (Capy, 2005). Autonome Retrotransposons untergliedern sich außerdem in LTR- (*long terminal repeats*) und Non-LTR-Retrotransposons.

LTR-Retrotransposons und die vermutlich aus ihnen entstandenen Retroviren ähneln sich in ihrer Struktur als auch in ihrem Transpositionsmechanismus (Xiong und Eickbush, 1990; Doolittle und Feng, 1992; Malik et al., 2000). Sie besitzen lange endständige Sequenzwiederholungen und kodieren für ein *gag* (*group specific antigen*)- und *pol* (Polyprotein)- Gen. Die Gag-Proteine bilden die Virus-ähnlichen Partikel (Abbildung 3). Das *pol*-Gen wiederum kodiert die zur Transposition nötigen Enzyme: Reverse Transkriptase, Ribonuklease H, Integrase und Protease (Doolittle et al., 1989). Retroviren besitzen im Unterschied zu den LTR-Retrotransposons zusätzlich ein *env*-Gen (*envelope*), welches die Infektiosität der Retroviren vermittelt und sie befähigt, die Wirtszelle zu verlassen (Bannert und Kurth, 2006). Der sich in der 5'-LTR befindende Promotor wird von der wirtseigenen RNA-Polymerase II erkannt, welche die mRNA transkribiert. Die reverse Transkription der mRNA in komplementäre DNA (cDNA) findet in Virus-ähnlichen Partikeln statt (Abbildung 3). Als Primer dient eine wirtseigene tRNA (Chapman et al., 1992). Diese bindet an eine Bindestelle unterhalb der 5'-LTR, wodurch eine kurze Minus-Strang-DNA (*minus-strang*

strong-stop) synthetisiert wird. Diese wird zur 3'-LTR transportiert und dient als Primer für die vollständige Minus-Strang-DNA-Synthese mit der Element-mRNA als Vorlage. Eine Polypurin-Bindestelle oberhalb der 3'-LTR dient als Startpunkt für die Synthese einer kurzen Plus-Strang-DNA (*plus-strang strong-stop*). Diese wiederum dient an der 5'-LTR als Primer für die Synthese der Plus-Strang-DNA, wobei die bereits synthetisierte Minus-Strang-DNA als Vorlage dient (Boeke und Corces, 1989; Boeke und Chapman, 1991). Nach Auflösen der Virus-ähnlichen Partikel erfolgt anschließend, mit Hilfe der Integrase, der Transport der linearen Doppelstrang-DNA in den Zellkern und die Integration ins Genom. Auch hier entstehen durch versetzten Doppelstrangbruch Sequenzverdopplungen (Sandmeyer *et al.*, 1990; Kim *et al.*, 1998).

Tyrosin-Rekombinase-Retrotransposons bilden eine eigenständige Gruppe innerhalb der Retrotransposons. Das Element DIRS (*Dictyostelium intermediate repeat sequence*) ist für diese Gruppe namensgebend. DIRS-ähnliche Elemente besitzen LTRs, jedoch sind diese im Vergleich zu den LTR-Retrotransposons nicht direkt wiederholt sondern invertiert (Goodwin und Poulter, 2001). Auch besitzen Tyrosin-Rekombinase-Retrotransposons eine interne komplementäre Region, die sowohl 5'-LTR als auch 3'-LTR komplementäre Sequenzen enthält (Poulter und Goodwin, 2005). Statt einer Integrase kodieren sie für eine Tyrosin-Rekombinase und bei der Integration ins Wirtsgenom entstehen keine Sequenzverdopplungen wie bei den LTR-Retrotransposons (Goodwin und Poulter, 2001). Ein möglicher Transpositionsmechanismus wird im nächsten Kapitel (3.2.1.) beschrieben.

Die Non-LTR-Retrotransposons besitzen keine LTRs. Stattdessen flankieren zwei untranslatierte Regionen (UTR) am 5'- und 3'-Ende des Elements (Abbildung 3) für gewöhnlich zwei offene Leserahmen (ORF). Der ORF2 kodiert die zur Retrotransposition nötigen Enzyme: Endonuklease und Reverse Transkriptase (Mathias *et al.*, 1991; Feng *et al.*, 1996). Für die Transposition assoziieren die ORF1- und ORF2-Proteine mit der elementeigenen mRNA (Dombroski *et al.*, 1991; Esnault *et al.*, 2000). Sie bilden dabei einen Ribonukleoproteinkomplex aus (Martin, 1991; Hohjoh *et al.*, 1996; Kulpa und Moran, 2005). Die Retrotransposition findet durch einen Mechanismus statt, der als *target primed reverse transcription* (TPRT) bekannt ist (Luan *et al.*, 1993). Während der TPRT schneidet die vom Element kodierte Endonuklease den Minus-Strang der Ziel-DNA, wodurch eine freie 3'-Hydroxylgruppe (3'-OH) entsteht (Feng *et al.*, 1996). Dieses freie 3'-OH-Ende dient der elementeigenen Reversen Transkriptase als Primer. Sie initiiert die cDNA-Synthese und nutzt die Element-mRNA als Vorlage (Feng *et al.*, 1996; Cost *et al.*, 2002; Kulpa und Moran, 2006). Dann wird vermutlich der zweite Strang der Ziel-DNA gespalten und der komplementäre DNA-Strang des Elements synthetisiert. Die Insertion erfolgt meist unter Erzeugung von Sequenzverdopplungen (Kazazian und Moran, 1998). Durch nicht vollständig

erfolgte reverse Transkription entstehen häufig 5'-trunkierte Kopien von Non-LTR-Retrotransposons, die zur Retrotransposition nicht mehr befähigt sind (Szak *et al.*, 2002).

Abb. 3: Transpositionsmechanismen von Klasse-I- und Klasse-II-Transposons. DNA-Transposons kodieren für eine Transposase, welche das Element aus dem Genom herausschneidet und an anderer Stelle wieder einfügt. LTR-Retrotransposons kodieren für Gag-Proteine, Protease, Reverse Transkriptase und Integrase. Gag-Proteine bilden die Virus-ähnliche Hülle. Dort wird die mRNA in cDNA umgeschrieben. Die Integrase fügt die Kopie des Elements ins Genom ein, Non-LTR-Retrotransposons besitzen am 5'- und 3'-Ende untranslatierte Regionen (UTR) und meist zwei offene Leserahmen (ORF), die für die zur Mobilisierung nötigen Proteine kodieren. RNA und ORF1- und ORF2-Proteine bilden einen Ribonukleoproteinkomplex. Die Retrotransposition erfolgt durch *target primed reverse transcription*. Tpase: Transposase, TE: transposables Element, LTR: *long terminal repeat*, RT: Reverse Transkriptase, PR: Protease, IN: Integrase, UTR: untranslatierte Region, ORF: *open reading frame*, pA: poly(A). (modifiziert nach Levin und Moran, 2011).

3.2.1 Transposons in *Dictyostelium discoideum*

Die ersten transposablen repetitiven Elemente wurden in *D. discoideum* 1983 beschrieben (Rosen *et al.*, 1983; Zuker *et al.*, 1983). Wie in Abbildung 4 zusammenfassend dargestellt, finden sich in *D. discoideum* sowohl putative DNA-Transposons als auch Retrotransposons.

Abb. 4: Transposable Elemente in *Dictyostelium discoideum*. Die Darstellung gibt eine Übersicht über die Transposons im Genom von *D. discoideum*, ihre jeweilige Größe und ihre Kopienzahl. Die grau unterlegten Zahlen zeigen den prozentualen Anteil der Transposongruppen am Genom von *D. discoideum*. Schwarz unterlegte Transposons integrieren in der Nähe von tRNAs. YR: Tyrosin-Rekombinase, LTR: long terminal repeat, bp: Basenpaare. (modifiziert nach Winckler et al., 2011).

Die DNA-Transposons im Genom von *D. discoideum* stellen einen Anteil von circa 1,5 %. Zu ihnen gehören Tdd-4 und Tdd-5, thug-S und thug-T und die *Dictyostelium*-DNA-Transposons DDT-A, DDT-B und DDT-S. Die Einteilung zu den DNA-Transposons ist bei all diesen Elementen allerdings hypothetisch, da die kodierten Proteine keine Homologien zu bekannten Transposasen zeigen (Winckler et al., 2011). Die größte Gruppe der mobilen Elemente in *D. discoideum* bilden die Retrotransposons mit einem prozentualen Anteil von ca. 8 %. Sie untergliedern sich in LTR- und Non-LTR-Retrotransposons sowie das Tyrosin-Rekombinase-Transposon DIRS-1 (siehe Abbildung 4). Den größten Teil der LTR-Retrotransposons bildet Skipper (Glöckner et al., 2001). Es ist zwar ein stark exprimiertes Element, weist dafür allerdings eine vergleichsweise geringe Kopienzahl auf (Glöckner et al., 2001; Winckler et al., 2005). Weitere zu den LTR-Retrotransposons zählende Elemente sind DGLT-A und DGLT-P (*Dictyostelium gypsy-like transposon*). DGLT-P gilt als ausgestorbenes Element, weil kein offener Leserahmen gefunden werden konnte (Glöckner et al., 2001). DGLT-A integriert in der Nähe von tRNA-Genen (Winckler et al., 2011). Den größten Anteil im Genom von *D. discoideum* stellen die sieben Non-LTR-Retrotransposons. Sie integrieren in genau definierten Abständen zu tRNA-Genen (Glöckner et al., 2001) und werden daher als *tRNA gene-targeted retroelements* oder kurz TREs bezeichnet (Winckler et al., 2005). TREs bevorzugen entweder Integrationsstellen oberhalb (5') von tRNA-Genen (TRE5-A, TRE5-B und TRE5-C) oder Integrationsstellen unterhalb (3') von tRNA-Genen (TRE3-A,

TRE3-B, TRE3-C und TRE3-D) (Szafranski et al., 1999; Glöckner et al., 2001). Durch ihre präzisen Integrationsabstände zu tRNA-Genen integrieren TREs nicht in bereits vorhandene Kopien von TRE-Elementen, sondern im definierten Abstand zum tRNA-Gen, wodurch dort eventuell bereits vorhandene Elemente verschoben werden und sich somit Tandems bilden können (Winckler et al., 2011).

In dieser Arbeit wurden insbesondere die Expressionen der Retroelemente DIRS-1 und TRE5-A untersucht. Deswegen sollen diese Elemente im Folgenden ausführlicher dargestellt werden.

DIRS-1

Das transposable Element DIRS-1 (*Dictyostelium intermediate repeat sequence 1*) unterscheidet sich von den anderen Retrotransposons aus *D. discoideum* durch invertierte terminale Wiederholungen, die fehlende DDE-Motiv-Integrase und die fehlende Proteasedomäne (Poulter und Goodwin, 2005; Wiegand et al., 2011). DIRS-1 besitzt stattdessen eine Tyrosin-Rekombinase, welche einen katalytischen Tyrosinrest zur Rekombination zweier doppelsträngiger DNA-Stränge nutzt (Poulter und Goodwin, 2005). Im *Dictyostelium*-Genom finden sich etwa 235 Kopien von DIRS-1 (Glöckner et al., 2001). Es ist ca. 4,8 kb groß, hat lange nicht identische invertierte terminale Wiederholungen (ITR) und beginnt und endet mit dem Trinukleotid TTT (T: Thymin) (Poulter und Goodwin, 2005). DIRS-1 weist drei sich überlappende offene Leserahmen auf (siehe Abbildung 5): Der erste kodiert für das mögliche Gag-Protein, der zweite für die Tyrosin-Rekombinase und der dritte schließlich für die Reverse Transkriptase, die Ribonuklease H und eine Methyltransferase (Piednoël et al., 2011). In der Nähe der 3'-ITR befindet sich eine interne komplementäre Region (ICR), die sowohl zur 5'-ITR als auch zur 3'-ITR komplementäre Sequenzen aufweist (Poulter und Goodwin, 2005).

Abb. 5: Schematische Darstellung des Tyrosin-Rekombinase-Transposons DIRS-1. DIRS-1 besteht aus drei sich überlappenden Leserahmen, umrandet von invertierten terminalen Wiederholungen (ITR). Am Ende des zweiten Leserahmens vor der 3'-terminalen Wiederholung findet sich die interne komplementäre Region (ICR). GAG: *gene specific antigen* (diese Proteine bilden den Nukleoproteinkomplex, in dem die reverse Transkription stattfindet); RT: Reverse Transkriptase; RH: Ribonuklease H; MT: Methyltransferase; YR: Tyrosin-Rekombinase. (modifiziert nach Poulter und Goodwin, 2005).

Im Vergleich zu den LTR-Retrotransposons weist DIRS-1 einen anderen Retrotranspositionsmechanismus auf. Die linke terminale Wiederholung besitzt Promotoraktivität und wird somit für die Transkription der mRNA benötigt (Cohen et al., 1984). Dabei handelt es sich um ein 4,5 kb großes Transkript mit drei sich überlappenden offenen Leserahmen (Capello et al., 1985). Die mRNA-Transkripte akkumulieren während der Entwicklung und beinhalten Teile der beiden langen terminalen Wiederholungen (Cohen et al., 1985; Wiegand et al., 2011). Durch die DIRS-1 eigene Reverse Transkriptase wird die mRNA in eine lineare cDNA transkribiert (Capello et al., 1985). Die Enden der cDNA enthalten Fragmente der beiden ITRs, die komplementär zur ICR sind. Die ICR bringt das 5'- und 3'-Ende der cDNA zusammen und dient als Vorlage, um die ITR-Sequenzen vollständig zu replizieren. Die anschließende Selbstligation erzeugt eine zirkuläre einzelsträngige DNA. Die aus dieser erzeugte doppelsträngige zirkuläre DNA inseriert abschließend mit Hilfe der Tyrosin-Rekombinase ins Genom von *D. discoideum* ohne Zielsequenzverdopplungen zu erzeugen (Capello et al., 1985; Poulter und Goodwin, 2005). Die Integration von DIRS-1 erfolgt in bereits vorhandene Kopien, so dass lange Transposon-Cluster erzeugt werden (Eichinger et al., 2005). DIRS-1 akkumuliert an jedem Ende aller sechs Chromosomen, wo diese Cluster womöglich die Zentromere von *D. discoideum* ausbilden (Eichinger et al., 2005; Glöckner und Heidel, 2009). Durch Hitzeschock und andere Stresssituationen kann die Transkription einer 900 Nukleotid langen *Antisense*-RNA hervorgerufen werden (Rosen et al., 1983; Zuker et al., 1983). Auch scheint die rechte LTR von DIRS-1 Promotoraktivität zu besitzen und ist vermutlich für die Transkription eines 4 kb großen *Antisense*-Transkripts verantwortlich (Wiegand et al., 2014). Die Regulation der DIRS-1-Expression in der Zelle erfolgt posttranskriptionell durch verschiedene Komponenten der RNA-Interferenz-Maschinerie (Boesler et al., 2014; Wiegand et al., 2014, siehe auch Abschnitt 3.4.1).

TRE5-A

Erste Studien zum Non-LTR-Retrotransposon TRE5-A wurden bereits im Jahr 1989 veröffentlicht (Marschalek et al., 1989). Es ist bekannt, dass *D. discoideum*-Zellen eine aktive Population dieses Retroelements enthalten (Beck et al., 2002; Siol et al., 2006). TRE5-A.1 ist das komplette rund 5,7 kb große, autonome Element. Es besitzt zwei offene Leserahmen (ORF), die von untranslatierten Regionen umrandet sind, welche wiederum in „Module“ eingeteilt sind (Marschalek et al., 1992; Abbildung 6). Das nicht-autonome TRE5-A.2 weist eine ORF2-Deletion auf und wird wahrscheinlich *in trans*, durch das ORF2-Protein von TRE5-A.1, mobilisiert (Beck et al., 2002; Winckler et al., 2002; Siol et al., 2006). Die Rekombination zwischen TRE5-A-Elementen führte mutmaßlich zur Deletion beider ORFs und damit zur Entstehung der „ABC-Minielemente“, welche TRE5-A.3 genannt werden (Winckler et al., 2002). Wie in Abbildung 6 dargestellt, bilden das A- und B-Modul die 5'-UTR

aus und das B- und C-Modul die 3'-UTR. Das A-Modul besitzt Promotoraktivität und führt zur Transkription der Plus-Strang RNA von TRE5-A (Schumann et al., 1994). Das B-Modul an der 5'-UTR bestimmt den Translationsstart von ORF1, seine Funktion in der Retrotransposition ist aber noch unbekannt (Siol et al., 2011). Das C-Modul von TRE5-A stellt einen schwachen Promotor dar, der die Transkription der *Antisense*-RNA von TRE5-A vermittelt (Schumann et al., 1997). Das A-Modul ist für die generelle Retrotransposition nicht nötig, sondern kann gegen andere Promotoren ausgetauscht werden (Siol et al., 2011). Dagegen ist das C-Modul beziehungsweise eine dort gebildete Sekundärstruktur für die Transposition essentiell (Siol et al., 2011). Der ORF1 von TRE5-A kodiert für ein 51 kDa großes Protein, das möglicherweise an TRE5-A-Transkripte bindet und dabei den für die Reverse Transkription und die anschließende Integration nötigen Ribonukleoproteinkomplex mit ausbildet (Winckler et al., 2002). Der ORF2 von TRE5-A kodiert für eine Reverse Transkriptase, eine Endonuklease und eine Cystein- und Histidin-reiche Domäne (Marschalek et al., 1992).

Abb. 6: Schematische Darstellung des Non-LTR-Transposons TRE5-A. TRE5-A besteht aus zwei sich überlappenden offenen Leserahmen, umrandet von untranslatierten Regionen. A,B,C: Module der untranslatierten Regionen; UTR: Untranslatierte Region; ORF: Offener Leserahmen (*open reading frame*); EN: Endonuklease; RT: Reverse Transkriptase; HC: Histidin- und Cystein-reiche Domäne. (modifiziert nach Winckler et al., 2005).

Wie die Transposition von TRE5-A erfolgt, ist bislang noch nicht genau bekannt. In Anlehnung an bekannte Non-LTR-Retrotranspositionsmechanismen erfolgt sie vermutlich über die sogenannte *target-primed reverse transcription* (Bilzer et al., 2011). Dabei bindet ORF2 vermutlich an das 3'-Ende der Transposon-RNA und transportiert diese zum Integrationsort. Dort wird die genomische DNA gespalten und die entstandene freie 3'-Hydroxylgruppe als Primer für die cDNA-Synthese genutzt (Feng et al., 1996). Nach erfolgter Retrotransposition sind viele der neuen Kopien von TRE5-A am 5'-Ende deletiert. Da sie dadurch keinen funktionellen Promotor mehr besitzen, sind sie nicht mehr mobilisierbar (Beck et al., 2002; Winckler et al., 2005). Die Integration erfolgt strikt positions- und orientierungsspezifisch rund 50 bp stromaufwärts von tRNA-Genen, wobei das 5'-Ende des integrierten Retrotransposons stets am 5'-Ende des tRNA-Gens liegt (Marschalek et al., 1989; Hofmann et al., 1991). Diese spezifische Integration erklärt sich womöglich durch den Kontakt von TRE5-A zu den Transkriptionsfaktoren (TF) der RNA-Polymerase III, welche die Transkription der tRNA Gene vermitteln (Siol et al., 2006). Nach dem derzeitigen Modell

bindet der RNA-Polymerase-III-Transkriptionsfaktor TFIIIC zuerst an die A- und B-Box, die Promotorelemente der tRNA-Gene. Nach erfolgreicher DNA-Bindung rekrutiert TFIIIC den Transkriptions-Initiationsfaktor TFIIIB. Das ORF1-Protein von TRE5-A interagiert dann mit einer Untereinheit des TFIIIB, dem TBP (TATA-Bindeprotein), und bestimmt somit den Integrationsort von TRE5-A (Siol et al., 2006; Chung et al., 2007; Winckler, 2013).

Beck et al. entwickelten 2002 ein Retrotranspositionssystem („TRE-Falle“, Abbildung 7), welches es ermöglicht, die Transpositionsfrequenz von TRE5-A *in vivo* zu bestimmen. Für diesen Test werden *D. discoideum*-Stämme verwendet, welche durch fehlende Expression einer Uridinmonophosphat-Synthase (UMPS) einen Defekt in der Pyrimidin-Neusynthese aufweisen. Die UMPS in *D. discoideum* wird vom *pyr5-6*-Gen kodiert und stellt ein bifunktionales Enzym dar, welches aus der Orotatphosphoribosyltransferase und der Orotidylatdecarboxylase besteht (Jacquet et al., 1988). Durch diese enzymatischen Aktivitäten kann Orotat in UMP umgebaut werden. Zellen mit defekter UMPS können kein UMP synthetisieren und sind Uracil-auxotroph (*ura*⁻). Sie benötigen von außen zugeführtes Uracil als Vorstufe für die Bildung von Pyrimidinbasen. Gleichzeitig sind *ura*⁻-Zellen resistent gegen das Zytostatikum 5-Fluoroorotat (5-FO): Durch die fehlende UMPS wird 5-FO nicht in 5-Fluoro-UMP umgewandelt, welches zu 5-Fluoro-Desoxy-UMP reduziert wird, einem irreversiblen Inhibitor der Thymidylat-Synthase. Im Retrotranspositionstest werden *ura*⁻-Zellen mit einem intakten UMPS-Gen transformiert und sind somit in der Lage, UMP zu bilden. Diese Zellen sind *ura*⁺. Das transformierte UMPS-Gen trägt in einem artifiziellen Intron ein tRNA-Gen, welches als Integrationsziel für TRE5-A-Elemente dient. In der Zelle wird das Intron inklusive des tRNA-Gens normal gespleißt, so dass funktionale UMPS entsteht. Die *ura*⁺-Zellen werden in einem Medium ohne Zusatz von Uracil selektioniert. Sobald aber ein Transpositionereignis am artifiziellen tRNA-Gen stattfindet, wird das UMPS-Gen durch Insertionsmutagenese inaktiviert. Die Zellen sind *ura*⁻ und können in Medium mit Zugabe von Uracil und 5-FO selektioniert werden. Demnach entspricht jeder in 5-FO selektionierte Klon einem Sprungereignis eines endogenen TRE5-As.

Abb. 7: Schematische Darstellung des Testsystems zur Bestimmung der *In-vivo*-Transpositionsfrequenz von TRE5-A in *D. discoideum*. Retrotranspositionssystem mit „TRE-Falle“. In 5-FO-haltigem Medium selektionierte Klone mit transformierter „TRE-Falle“ entsprechen einem Sprungereignis von TRE5-A. ura⁻: Uracil-auxotroph; ura⁺: Bildung Uracil; 5-FO: 5-Fluoroorotat.

3.3 Der C-Modul-bindende Faktor A

Der C-Modul-bindende Faktor A (CbfA) wurde bei der Suche nach Proteinen entdeckt, die *in vitro* an das C-Modul von TRE5-A aus *D. discoideum* binden (Geier et al., 1996). Das Gen *cbfA* befindet sich auf Chromosom 3 an der Position 2308619 bis 2312032, umfasst 3414 bp und wird von einem Intron mit einer Länge von 412 bp unterbrochen (Horn et al., 1999). Das Protein CbfA hat eine Länge von 1000 Aminosäuren mit einem Molekulargewicht von 115 kDa und besitzt drei Proteindomänen (siehe Abbildung 8). Am N-Terminus befindet sich die hoch konservierte JmjC/ZF-Region: Von Aminosäure 113 bis 280 befindet sich die Jumonji-Domäne (JmjC), die eine signifikante Ähnlichkeit zur Jumonji-Domäne des murinen Jumonji-Proteins aufweist (Takeuchi et al., 1995). Von Aminosäure 373 bis 414 und von 492 bis 550 finden sich die zwei Zinkfinger-ähnlichen Domänen (ZF). Eine Asparagin-reiche Region mit einer Länge von 217 Aminosäuren und einem Anteil an Asparagin-Resten von rund 50 % trennt die JmjC/ZF-Domäne von der C-terminalen Domäne (CTD). Die CTD hat eine Länge von 230 Aminosäuren und trägt den AT-Haken (A: Adenin; T: Thymin; Winckler et al., 2004; Lucas et al., 2009). Der AT-Haken mit seinem zentralen GRP-Motiv (G: Glycin, R: Arginin, P: Prolin) ist für die Bindung von CbfA an die AT-reiche DNA-Sequenz des C-

Moduls von TRE5-A über die kleine Furche der DNA essentiell (Horn et al., 1999). Die CTD konnte als eigenständige genregulatorische Einheit identifiziert werden (Lucas et al., 2009). Dafür wurden GFP-CTD-Fusionsproteine in sowohl Wildtyp- als auch in CbfA-depletierten Zellen (JH.D, siehe unten) exprimiert und die allgemeine Genexpression in beiden Stämmen mit Hilfe von *Microarray*-Experimenten überprüft und verglichen. Dabei konnten viele unterschiedliche Gene identifiziert werden, die allein durch die CTD von CbfA reguliert werden können (Lucas et al., 2009). Die Funktion der anderen Domänen ist noch unklar. Die JmjC-Domäne könnte eine Chromatin modifizierende Aktivität besitzen, da JmjC-Domänen-Proteine an der Demethylierung von Arginin- und Lysin-Aminogruppen in Histonen beteiligt sind (Trewick et al., 2005; Tsukada et al., 2006). Ein entsprechender Nachweis steht für CbfA jedoch noch aus.

Abb. 8: Schematische Darstellung von CbfA. Die Struktur von CbfA besteht aus der JmjC/ZF-Region, die sich aus der C-terminalen Jumonji-Domäne (JmjC) und zwei Zinkfinger-Motiven (ZF) zusammensetzt, gefolgt von einer Asparagin-reichen (NRD) und der C-terminalen Domäne (CTD) mit AT-Haken und GRP-Motiv mit essentiell zentralem Arginin zur Bindung an Adenin- und Thymin-reiche (AT)-Sequenzen. (modifiziert nach Lucas et al., 2009).

Um mehr über die Funktion des Transkriptionsregulators zu erfahren, wurde versucht, das Gen *cbfA* im haploiden Genom von *D. discoideum* durch homologe Rekombination zu zerstören. Da diese Versuche misslangen, wurde geschlussfolgert, dass es sich bei CbfA vermutlich um ein für die Zelle essentielles Protein handeln könnte (Horn et al., 1999; Winckler et al., 2001). Daher wurde versucht, Mutanten mit geringer Expression von CbfA zu generieren. In ein genomisches Fragment von *cbfA* wurde zwischen den beiden Zinkfinger-Domänen ein *Amber*-Stoppkodon (UAG) eingeführt. Anschließend wurden in den dieses Fragment tragenden Vektor ein Suppressor-tRNA-Gen und eine Blasticidin-Resistenzkassette eingefügt. Dieses Konstrukt wurde in *D. discoideum*-Zellen transformiert. Über homologe Rekombination erfolgte der *Knockin* des Konstrukts, wobei ein Teil des *cbfA*-Gens 3' verschoben wurde. In der entstandenen Mutante JH.D existieren zwei *cbfA*-Kopien: Eine 5' verkürzte, nicht-exprimierte und eine das *Amber*-Stoppkodon tragende vollständige Kopie (Winckler et al., 2001). Da *D. discoideum* nur in rund 4 % der Gene UAG als Stoppkodon nutzt, wird die Expression der tRNA^{Glu} (CUA) toleriert, ohne Phänotypen zu erzeugen (Dingermann et al., 1990; Winckler et al., 2001). In der Mutante JH.D wird zu etwa

5 % das *Amber*-Stoppkodon im modifizierten *cbfA*-Gen von der Suppressor-tRNA erkannt. Dadurch kommt es zum Einbau von Glutaminsäure und der Expression eines kompletten CbfA-Proteins. Jedoch wird zu ca. 95 % die Translation am *Amber*-Stoppkodon abgebrochen. Der verkürzten Form von CbfA fehlt die CTD und sollte daher nicht mehr an seine Zielsequenzen binden können und somit nicht mehr funktionell sein (Winckler et al., 2001).

JH.D zeigt einen starken Entwicklungsdefekt (siehe Abbildung 9), weil Gene, die für die multizelluläre Entwicklung benötigt werden, nicht exprimiert werden können (Winckler et al., 2004). Die Ursache dafür liegt möglicherweise in der fehlenden Bindung von CbfA an den *acaA*-Promotor (Siol et al., 2006a). Durch die dann fehlende Expression der Adenylatzyklase A (ACA) sind *D.-discoideum*-Zellen nicht in der Lage, cAMP für die interzelluläre Kommunikation während der Aggregation zu bilden. Somit werden auch alle durch cAMP-Pulse induzierten, für die späte multizelluläre Entwicklung nötigen Gene nicht aktiviert (Winckler et al., 2004; Siol et al., 2006a). Dieser Aggregationsdefekt kann jeweils durch die Expression von rekombinantem CbfA, die Expression rekombinanter ACA, die Mischung von JH.D- und Wildtypzellen sowie die Gabe von cAMP-Pulsen ganz oder teilweise behoben werden (Winckler et al., 2004; Siol et al., 2006a).

Abb. 9: Entwicklungsdefekt von JH.D. CbfA wird in JH.D nur noch zu 5 % exprimiert. JH.D ist zur multizellulären Entwicklung nicht mehr fähig. Abgebildet sind sich vollständig entwickelte Fruchtkörper von Wildtypzellen (WT) im Vergleich zur Entwicklungsmutante JH.D. (Quelle: Eigene Daten).

3.4 RNA-Interferenz

Im Jahr 1998 injizierten Fire und Mello doppelsträngige RNA (dsRNA) in *Caenorhabditis elegans* und entdeckten, dass diese dsRNA zum Abbau der komplementären mRNA in *C. elegans* führte (Fire et al., 1998). Der Prozess der Genstilllegung über dsRNA ist als RNA-Interferenz (RNAi) bekannt. RNAi ist in fast allen Eukaryoten vorhanden (Dogini et al., 2014). Dieser Prozess kann experimentell genutzt werden, um beispielsweise Genfunktionen zu identifizieren oder essentielle Gene von Pathogenen auszuschalten. Damit entwickelte sich RNAi zu einem wichtigen Werkzeug der Molekularbiologie (Dogini et al., 2014).

Abb. 10: Schematische Darstellung zellulärer RNAi-Prozesse. Dicer- und RISC-Komplexe sind verantwortlich für den Abbau von viraler RNA (1) und Transposontranskripten (2). Sie blockieren die Proteinsynthese durch Prozessierung und Ladung kleiner in der Zelle generierter RNAs (3) und spielen eine Rolle in der RNAi-vermittelten Inhibierung der Translation (4). Auch werden diese Komplexe genutzt, um experimentell spezifische Gene auszuschalten (5). (modifiziert nach www.nobelprize.org/nobel_prizes/medicine/laureates/2006/advanced.html).

Der generelle Ablauf der RNAi unterteilt sich in drei wesentliche Schritte: I.) Endo- oder exogene lange dsRNAs, die beispielhaft von Viren oder Transposons stammen, werden von Ribonuklease-III-ähnlichen Dicer-Enzymen in kleine sogenannte siRNAs prozessiert (Abbildung 10, Bernstein et al., 2001). II.) Diese kleinen siRNAs werden entwunden und ein Strang wird in einen Proteinkomplex geladen, der als *RNA-induced silencing complex* (RISC) bekannt ist (Abbildung 10, Tuschl et al., 1999; Hammond et al., 2000). III.) Die geladene

siRNA führt den Proteinkomplex zu komplementären Ziel-mRNAs, die vom Argonauten-Protein – als Kernkomponente von RISC – degradiert werden (Siomi und Siomi, 2009). Außerdem kann RISC die Proteinsynthese inhibieren und Chromatin modifizieren (Abbildung 10, Malone und Hannon, 2009). RNAi-Mechanismen sind ebenfalls an transkriptionellen Gen-*Silencing*-Prozessen beteiligt. Dabei rufen doppelsträngige RNA-Moleküle womöglich die Methylierung von Promotorsequenzen hervor, wodurch Promotoren, wahrscheinlich durch Chromatinkondensation (Abbildung 10), inaktiviert werden (Sijen et al., 2001). Die an RNAi beteiligten kleinen RNAs sind *small interfering* (si), *micro* (mi) und *piwi-interacting* (pi) RNAs. siRNAs mit einer Länge von 21 Nukleotiden (nt) sind an der Genomregulation und der Abwehr von Viren und Transposons beteiligt (Ghidiyal und Zamore, 2009; Malone und Hannon, 2009). Die 26 bis 33 nt langen piRNAs binden an Argonauten-Proteine der PIWI-Klade. Ihre Biogenese erfolgt Dicer-unabhängig in einem Amplifizierungsprozess, der als *ping-pong loop* bezeichnet wird. Sie sind an der Regulation der Chromatin-Beschaffenheit und der Transposonaktivität beteiligt (Ghidiyal und Zamore, 2009; Malone und Hannon, 2009; Meister, 2013). Die miRNAs mit einer Länge von 22 nt durchlaufen ebenfalls einen anderen Syntheseweg. Ihre Vorläufer-RNAs werden von der RNA-Polymerase II transkribiert und bilden doppelsträngige *Hairpin*-Moleküle (Abbildung 10) aus. Diese werden von Drosha, einem RNase-Typ-III-Enzym, erkannt, gespalten und schließlich von Dicer zu miRNA-Dimeren prozessiert (Meister, 2013).

Argonauten-Proteine sind die Kernkomponente des RISC. Die Familie der Argonauten-Proteine wird in drei Klassen unterteilt: Die AGO-Proteine, die ähnlich zu AGO1 aus *Arabidopsis thaliana* sind, des Weiteren die PIWI-Proteine, die homolog zu Piwi aus *Drosophila melanogaster* sind und schließlich die Proteine der WAGO-Klade, die in *C. elegans* anzutreffen sind (Meister, 2013). Argonauten-Proteine besitzen eine variable N-terminale Domäne, eine PAZ (*piwi-argonaute-zwille*)-, eine MID (*middle*)- und eine PIWI (*P-element induced wimpy testis*)-Domäne. Die PAZ-Domäne verankert das 3'-Ende, die MID-Domäne das 5'-Ende der kleinen RNA. Die N-terminale Domäne wird für die Ladung der RNA und deren Entwindung benötigt. Die PIWI-Domäne ähnelt der Ribonuklease H, agiert als Endonuklease und spaltet die Ziel-RNA (Meister, 2013).

Einige Organismen verwenden auch RNA-abhängige RNA-Polymerasen (RdRP) für die zellulären RNAi-Prozesse. RdRPs nutzen einzelsträngige RNAs als Vorlage zur Amplifizierung komplementärer RNAs. Die entstehenden dsRNAs können somit das initiale *Silencing*-Signal verstärken (Cerutti und Casas-Mollano, 2006; Wassenegger und Krezal, 2006; Maida und Masutomi, 2011). Dabei werden die dsRNAs von Dicer-Proteinen zu sekundären siRNAs prozessiert, die wiederum erneut in RISC-Komplexe geladen werden können (Girard und Hannon, 2008). RdRPs sind auch verantwortlich für einen als

Transitivität bekannten Prozess. In diesem entstehen sekundäre siRNAs, und damit *Silencing*-Signale, außerhalb von Regionen, die ursprünglich von dsRNAs getriggert wurden (Voinnet et al., 1998; Sijen et al., 2001; Vaistij et al., 2002).

3.4.1 RNAi in *Dictyostelium discoideum*

In *D. discoideum* konnten viele Komponenten identifiziert werden, die für ein funktionales RNA-Interferenz-System entscheidend sind. So finden sich zwei Dicer-ähnliche Proteine DrnA und DrnB, drei RNA-abhängige RNA-Polymerasen (RdRP) RrpA, RrpB und RrpC und die fünf PIWI-ähnlichen Argonauten-Proteine AgnA bis AgnE (Cerutti und Casas-Mollano, 2006). Auch das Vorhandensein kleiner regulatorischer RNAs wie siRNAs und miRNAs deuten auf die Präsenz eines aktiven RNAi-Systems in *D. discoideum* (Hinas et al., 2007). Bislang ist allerdings nur wenig über die Funktionen der einzelnen Komponenten bekannt. Den aktuellen Stand in der Erforschung der posttranskriptionellen RNA-Regulation in *D. discoideum* soll nun dieses Kapitel geben.

Die zwei Dicer-ähnlichen Proteine DrnA und DrnB besitzen keine N-terminale Helikase-Domäne, welche in Dicer-Proteinen anderer Organismen konserviert ist (Martens et al., 2002; Cerutti und Casa-Mollano, 2006). Dieses Motiv findet sich allerdings in den RdRPs von *D. discoideum*, möglicherweise durch einen Domänen austausch zwischen Dicer und RdRPs (Martens et al., 2002). DrnB ist für die Prozessierung von miRNAs aus ihren Vorläufer-dsRNAs verantwortlich und auch an der Bildung sekundärer siRNAs beteiligt (Hinas und Söderbom, 2007; Avesson et al., 2012; Wiegand und Hammann, 2013).

Die drei in *D. discoideum* vorhandenen RdRP-Homologe RrpA, RrpB und RrpC besitzen am N-Terminus eine Helikase-Domäne und eine RdRP-homologe Domäne (Martens et al., 2002). RrpA und RrpB sind sich sehr ähnlich und unterscheiden sich nur in 49 von rund 2400 Aminosäuren. Das weniger konservierte RrpC zeigt dennoch Ähnlichkeit zu allen RdRPs anderer Organismen (Martens et al., 2002). Alle drei RdRPs sind an der Regulation der beiden Retrotransposons Skipper und DIRS-1 beteiligt: So führt das Ausschalten von *rrpC* zur Erhöhung der Expression von DIRS-1. In Stämmen, in denen die Expression aller drei *rrps* nicht mehr vorhanden ist, kann jeweils eine Expressionserhöhung von Skipper verzeichnet werden (Kuhlmann et al., 2005). Mittlerweile existieren *Knockout*-Stämme aller drei *rrp*-Gene, darunter ein *Triple-Knockout*, woraus geschlossen werden kann, dass diese Gene für *D. discoideum* nicht essentiell sind (Wiegand und Hammann, 2013). In der *rrpC*-Mutante akkumulieren sowohl *Sense*- als auch *Antisense*-Transkripte von DIRS-1 und die

Anzahl kleiner RNAs nimmt signifikant ab. Dies führt wiederum zur Translation der DIRS-1-Proteine und zur erfolgreichen Retrotransposition des Transposons (Wiegand et al., 2014).

Abb. 11: Schematische Darstellung der Argonauten-Proteine von *D. discoideum*. Alle in *D. discoideum* vorhandenen Argonauten-Proteine besitzen sowohl eine RNA-bindende PAZ-Domäne als auch eine katalytische PIWI-Domäne mit Endonuklease-Aktivität. Agn: Argonauten-Protein; PAZ: *piwi-argonaute-zwille*; PIWI: *P-element induced wimpy testis*. (modifiziert nach Boesler et al., 2014).

Im Genom von *D. discoideum* kodieren fünf Gene für PIWI-ähnliche Proteine (AgnA bis E), die je eine PAZ- und eine PIWI-Domäne aufweisen (siehe Abbildung 11, Cerutti und Casas-Mollano, 2006). Über die Funktion der Argonauten-Proteine in *D. discoideum* ist bisher nicht viel bekannt. Boesler et al. konnten jedoch 2014 zeigen, dass AgnA an der DIRS-1-Regulation beteiligt ist. Ähnlich wie bei RrpC akkumulieren DIRS-1-Transkripte im *agnA*-Stamm und die Menge kleiner interferierender RNAs (siRNA) von DIRS-1 nimmt ab (Boesler et al., 2014).

4. Zielsetzung der vorliegenden Arbeit

Dictyostelium discoideum ist ein eukaryotischer Organismus aus der Gruppe der *Amoebozoa*. Trotz seines kompakten, haploiden Genoms mit einer hohen Gendichte weist *D. discoideum* eine hohe Anzahl an transposablen Elementen auf. Diese DNA-Sequenzen sind befähigt, an neuen Positionen im Genom zu integrieren. Klassifiziert werden diese Elemente in DNA-Transposons und Retrotransposons. Zu den Retrotransposons in *D. discoideum* gehören unter anderem DIRS-1 und TRE5-A. DIRS-1 akkumuliert an jeweils einem Ende der sechs Chromosomen von *D. discoideum* in bereits vorhandene DIRS-1-Kopien und trägt vermutlich zur Ausbildung der Centromere bei. TRE5-A integriert sehr spezifisch oberhalb von tRNA-Genen. Da sowohl von DIRS-1 als auch TRE5-A *Sense*- und *Antisense*-Transkripte gebildet werden, wird eine Regulation beider Elemente durch das zelleigene RNA-Interferenz-System (RNAi) vermutet. Ein Ziel dieser Arbeit war es, herauszufinden, ob TRE5-A und DIRS-1 tatsächlich von RNAi reguliert werden und die Proteine zu identifizieren, die daran beteiligt sind. Durch den Vergleich von TRE5-A und DIRS-1 sollten Unterschiede in der Regulation beider Elemente durch RNAi untersucht werden.

Vorangegangene Arbeiten mit *Microarray*-Experimenten konnten den C-Modul-bindenden Faktor A (CbfA) als generellen Transkriptionsregulator in *D. discoideum* und dessen Carboxy-terminale Domäne (CTD) als eigenständige genregulatorische Einheit identifizieren. In der Mutante JH.D, welche CbfA nur noch zu etwa 5 % im Vergleich zum Wildtyp exprimiert, konnte eine Reduktion der TRE5-A-Expression um bis zu 90 % ermittelt werden. Es sollte in dieser Arbeit daher untersucht werden, ob ein Zusammenhang zwischen RNAi-basierter Regulation von TRE5-A und der Aufrechterhaltung der TRE5-A-Expression durch CbfA besteht. Dabei sollten unter anderem RNA-Seq-Analysen der CbfA-abhängigen Genexpression von Wildtyp und JH.D miteinander verglichen und die vorhandenen *Microarray*-Daten vervollständigt werden.

Begleitend sollte eine phylogenetische Analyse der Domänenstruktur von CbfA innerhalb der sozialen Amöben weiteren Aufschluss über die Funktionen einzelner Domänen von CbfA bei der allgemeinen Genregulation und speziell bei der Regulation von Transposons geben.

5. Übersicht der Manuskripte

Manuskript 1:

The C-Module-Binding Factor Supports Amplification of TRE5-A Retrotransposons in the *Dictyostelium discoideum* Genome

Annika Bilzer, Heike Dölz, Alexander Reinhardt, **Anika Schmith**, Oliver Siol und Thomas Winckler

Publiziert in *Eukaryotic Cell*, 2011.

Inhaltsangabe: Der C-Modul-bindende Faktor A (CbfA) bindet *in vitro* an das C-Modul des Non-LTR-Retrotransposons TRE5-A. In diesem Artikel konnte gezeigt werden, dass die Akkumulation der *Sense*- als auch der *Antisense*-Transkripte von TRE5-A von CbfA abhängig ist. Auch die Retrotransposition von TRE5-A wird positiv von CbfA reguliert. Keiner der beiden internen Promotoren von TRE5-A wird dabei von CbfA reguliert. Daher wird in diesem Artikel spekuliert, dass CbfA TRE5-A indirekt reguliert, indem es Komponenten der posttranskriptionellen Gen-*Silencing*-Maschinerie supprimiert.

Eigenanteil: Der Hauptteil dieser Arbeit wurde von Annika Bilzer durchgeführt. Ich war an der Durchführung der qRT-PCR-Experimente und deren Auswertung beteiligt. Das Manuskript wurde in Zusammenarbeit von Thomas Winckler und Annika Bilzer verfasst und von mir Korrektur gelesen.

Manuskript 2:

Conserved Gene Regulatory Function of the Carboxy-Terminal Domain of Dictyostelid C-Module-Binding Factor

Anika Schmith, Marco Groth, Josephine Ratka, Sara Gatz, Thomas Spaller, Oliver Siol, Gernot Glöckner, Thomas Winckler

Publiziert in *Eukaryotic Cell*, 2013.

Inhaltsangabe: In dieser Arbeit konnte mit Hilfe von Transkriptomanalysen gezeigt werden, dass es sich bei CbfA um einen generellen Transkriptionsregulator handelt, der Genexpression positiv und negativ beeinflussen kann. Ein von CbfA stark supprimiertes Gen kodiert für das Argonauten-Protein AgnC, welches eine Komponente der RNA-Interferenz-

Maschinerie in *D. discoideum* darstellt. Des Weiteren konnte bestätigt werden, dass die C-terminale Domäne von CbfA eine eigenständige genregulatorische Einheit ist, die an der TRE5-A-Regulation beteiligt ist. Es konnte gezeigt werden, dass CbfA in der Familie der sozialen Amöben strukturell und funktionell stark konserviert wurde.

Eigenanteil: Alle Experimente zur Herstellung der Transformanten wurden von mir ausgeführt. Die Transkriptomanalysen wurden am Leibnitz-Institut für Altersforschung Jena von Marco Groth durchgeführt. Ich war an der Auswertung der Daten beteiligt und habe die qRT-PCR-Experimente zur Bestätigung der Daten durchgeführt. Die phylogenetischen Analysen erstellte ich zusammen mit Thomas Spaller. Das Manuskript wurde von Thomas Winckler und mir verfasst.

Manuskript 3:

The *Dictyostelium discoideum* RNA-dependent RNA polymerase RrpC silences the centromeric retrotransposon DIRS-1 post-transcriptionally and is required for the spreading of RNA silencing signals

Stephan Wiegand, Doreen Meier, Carsten Seehafer, Marek Malicki, Patrick Hofmann, **Anika Schmith**, Thomas Winckler, Balint Földesi, Benjamin Boesler, Wolfgang Nellen, Johan Reimegard, Max Käller, Jimmie Hällman, Olof Emanuelsson, Lotta Avesson, Frederik Söderbom und Christian Hammann

Publiziert in *Nucleic Acids Research*, 2014.

Inhaltsangabe: In dieser Arbeit wurde gezeigt, dass RrpC als Komponente der RNA-Interferenz-Maschinerie in *D. discoideum* das Retrotransposon DIRS-1 posttranskriptionell supprimiert. In *rrpC-Knockout*-Stämmen akkumulieren DIRS-1-Transkripte, siRNAs von DIRS-1 verschwinden und die Transposon-Mobilität nimmt zu. Außerdem konnte dargestellt werden, dass RrpC an der Verbreitung von RNA-Silencing-Signalen beteiligt ist.

Eigenanteil: Der Großteil der Experimente wurde in der Arbeitsgruppe von Prof. Christian Hammann durchgeführt. Die im Artikel enthaltenen qRT-PCR-Daten zur Überprüfung der durch Northern Blots ermittelten DIRS-1-Expression in den Mutanten wurden von mir generiert und ausgewertet. Das Manuskript wurde von mir Korrektur gelesen.

Manuskript 4:

A host factor supports retrotransposition of the TRE5-A population in *Dictyostelium* cells by suppressing an Argonaute protein

Anika Schmith, Thomas Spaller, Åsa Fransson, Jonas Kjellin, Benjamin Boesler, Sandeep Ojha, Wolfgang Nellen, Christian Hammann, Fredrik Söderbom, Thomas Winckler

Publiziert in *Mobile DNA*, 2015.

Inhaltsangabe: Mit dieser Arbeit konnte belegt werden, dass CbfA die Transposition von TRE5-A positiv beeinflusst, indem es die Expression des Argonauten-Proteins AgnC inhibiert. Durch die Supprimierung von AgnC durch CbfA, können TRE5-A-Transkripte akkumulieren und als Substrat für die Retrotransposition des Elements dienen. Somit konnte gezeigt werden, dass die Amplifikation von TRE5-A in *D. discoideum* zwar von RNA-Interferenz unterdrückt wird, dies aber teilweise durch den zellulären Faktor CbfA wieder aufgehoben werden kann.

Eigenanteil: Alle experimentellen Arbeiten in diesem Paper wurden von mir durchgeführt und die erhaltenen Daten von mir analysiert. Das Manuskript wurde von Thomas Winckler und mir verfasst.

Received 23 August 2010/Accepted 4 November 2010

Retrotransposable elements are molecular parasites that have invaded the genomes of virtually all organisms. Although retrotransposons encode essential proteins to mediate their amplification, they also require assistance by host cell-encoded machineries that perform functions such as DNA transcription and repair. The retrotransposon TRE5-A of the social amoeba *Dictyostelium discoideum* generates a notable amount of both sense and antisense RNAs, which are generated from element-internal promoters, located in the A module and the C module, respectively. We observed that TRE5-A retrotransposons depend on the C-module-binding factor (Cbfa) to maintain high steady-state levels of TRE5-A transcripts and that Cbfa supports the retrotransposition activity of TRE5-A elements. The carboxy-terminal domain of Cbfa was found to be required and sufficient to mediate the accumulation of TRE5-A transcripts, but it did not support productive retrotransposition of TRE5-A. This result suggests different roles for Cbfa protein domains in the regulation of TRE5-A retrotransposition frequency in *D. discoideum* cells. Although Cbfa binds to the C module *in vitro*, the factor regulates neither C-module nor A-module promoter activity *in vivo*. We speculate that Cbfa supports the amplification of TRE5-A retrotransposons by suppressing the expression of an as yet unidentified component of the cellular posttranscriptional gene silencing machinery.

Retrotransposons are ancient mobile elements that amplify in eukaryotic cells via reverse transcription of RNA intermediates (6). Because genomic integration of retrotransposon-derived cDNA is a default mechanism in the amplification of these elements, their activity causes a constant threat of insertion mutagenesis and genome instability in host genomes. This threat may be particularly important if the host cell has a haploid and compact genome, such as that of the social amoeba *Dictyostelium discoideum*, in which some 67% of nuclear DNA codes for proteins (7). *D. discoideum* mobile elements display two different regional integration preferences (reviewed in reference 28). The first group of mobile elements shows a strong bias toward inserting into preexisting copies of the same or similar elements, thereby forming large clusters in certain chromosomal regions that rarely contain protein coding capacity. A second group of retrotransposons has developed mechanisms to actively target sites in the close vicinity of tRNA genes as landmarks for “safe” integration. These elements are therefore called “tRNA gene-targeting retroelements” (TREs) (25). Because tRNA genes are scattered throughout all *D. discoideum* chromosomes and offer approximately 400 different integration sites, TREs have managed to colonize all regions of the *D. discoideum* genome.

We recently showed that TRE5-A maintains an active population in *D. discoideum* cells (2, 23). TRE5-A forms two major subpopulations, referred to as TRE5-A.1 and TRE5-A.2. These elements were formerly known as DREa and DREb (18, 19). TRE5-A.1 represents the full-length retrotransposition-

competent element, whereas TRE5-A.2 has an extended ORF2 deletion and is probably mobilized *in trans* by TRE5-A.1 (2, 23). Considering the amino acid similarity of the TRE5-A ORF2 protein with other non-long terminal repeat (LTR) retrotransposons (15, 16), it is most likely that TRE5-A retrotransposition involves a coupled reverse transcription and integration process known as target-primed reverse transcription (5, 13). *In vitro* experiments suggest that TRE5-A may identify tRNA genes as integration sites by making contact between the TRE5-A-encoded ORF1 protein, as part of a preintegration complex, and the TATA-binding protein that is part of the tRNA gene-specific transcription complex TFIIB (4, 23).

In growing *D. discoideum* cells, TRE5-A is well expressed in both directions from element-internal promoters that are recognized by RNA polymerase II (22). Plus-strand RNA [(+) RNA] is produced by a promoter located within the A module in the 5'-untranslated region of the element. Antisense RNA [(-) RNA] is generated by the C-module promoter at the 3' end of the TRE5-A element (22). A C-module-binding factor (Cbfa) was purified and characterized based on its *in vitro* binding to the C module of TRE5-A in electrophoretic mobility shift assays (9, 10, 24, 27, 29). The Cbfa protein spans 1,000 amino acids and contains a “carboxy-terminal Jumonji domain” (JmjC), two zinc finger-like motifs of unknown function, an asparagine-rich domain, and a distinct carboxy-terminal domain (referred to here as Cbfa-CTD). JmjC domains are thought to catalyze the oxidative demethylation of histone tails in chromatin (reviewed in references 1, 11, and 26), thereby contributing to the epigenetic control of gene transcription. It is currently unknown whether Cbfa has chromatin-remodeling activity.

DNA microarray analyses have indicated that Cbfa regulates at least 160 genes during the growth phase of *D. discoi-*

deum (14). CbfA is also essential to initiating the multicellular life cycle of *D. discoideum* cells, probably because CbfA mutants are unable to induce the adenylyl cyclase that generates the cyclic AMP required for intercellular signaling during aggregation (27). Interestingly, DNA microarray analyses have also revealed a gene regulatory function of CbfA-CTD that does not require the remainder of the CbfA protein. In fact, some 50% of CbfA-dependent genes are regulated exclusively by CbfA-CTD (14).

Here we show that the retrotransposition of TRE5-A in *D. discoideum* cells depends on a functional CbfA protein. Whereas CbfA-CTD is sufficient to maintain high steady-state levels of both (+) RNA and (–) RNA of TRE5-A, it does not support productive retrotransposition of these TRE5-A transcripts in the absence of the full-length CbfA protein. This finding suggests different roles for CbfA protein domains in the regulation of the TRE5-A retrotransposition frequency in *D. discoideum* cells.

MATERIALS AND METHODS

In vivo retrotransposition assay (TRE trap assay). JH.D[ura[–]] cells were derived from strain JH.D (29) by prolonged selection of cells in the presence of 100 µg/ml 5-fluoroorotic acid (5-FOA) and 20 µg/ml uracil. DH1[ura[–]] (3) and JH.D[ura[–]] cells were cultured either in HL5 medium or in FM medium supplemented with 20 µg/ml uracil. The TRE trap assay was performed as described by Siol et al. (23). Briefly, DH1[ura[–]] or JH.D[ura[–]] cells were transformed with a plasmid carrying a *D. discoideum* *pyr5-6* gene whose reading frame was disrupted by an artificial intron. A *D. discoideum* Val^{UAC} tRNA gene was inserted into the intron as bait to attract TRE5-A integrations. These constructs are referred to as TRE^{trap} genes. TRE^{trap}-carrying plasmids were transformed into DH1[ura[–]] or JH.D[ura[–]] cells, and transformants were selected in FM medium in the absence of uracil. DH1[ura⁺/TRE^{trap}] or JH.D[ura⁺/TRE^{trap}] cells were cultured further in HL5 medium and were supertransformed either with plasmid pDXA-rCbfA, expressing nearly full-length CbfA²⁻⁹⁹⁸ (27), or with pDXA-CTD, expressing the carboxy-terminal domain of CbfA (CbfA-CTD; CbfA⁷²⁴⁻⁹⁹⁸) (14). Stable transformants were obtained by selection in HL5 medium containing 4 µg/ml G418. To select for *de novo* retrotransposition events, 10⁷ cells of the respective transformants were cultured in FM medium in the presence of 250 µg/ml 5-FOA and 30 µg/ml uracil, as described previously (2, 23). TRE^{trap}/ura[–] clones from five different plates were counted, and mean values ± standard deviations (SD) are presented. Each experiment was repeated at least twice.

Luciferase reporter assay. An A module of TRE5-A.1 was amplified by PCR from plasmid pB3 (18) and inserted into pGEM-T (Promega). A firefly luciferase gene, including the downstream *cotB* (*sp70*) terminator, was isolated as a HindIII/SpeI fragment from plasmid pVTAL-AL (12) and then ligated into the primer-derived HindIII site downstream of the A module and the vector-derived SpeI site of pGEM-T. The resulting vector was named pGEM-A-luc. In this vector, the A module was replaced by a PCR-amplified C module to generate pGEM-C-luc. The reporter plasmids were cotransformed with pISAR (17) into *D. discoideum* AX2 and JH.D cells, and stable transformants were selected in HL5 medium containing 10 µg/ml or 7.5 µg/ml G418, respectively. Cells from plates containing at least 50 clones were pooled, and the copy number of the luciferase reporter gene was determined by quantitative PCR analysis of genomic DNA preparations. Cells from individual pools were grown in shaken cultures in HL5 medium supplemented with G418. Logarithmically growing cells were washed and frozen as cell pellets of 2 × 10⁷ cells at –80°C until further use. Frozen cells were lysed by adding 200 µl of phosphate-buffered saline (PBS). Aliquots corresponding to 2 × 10⁶ cells were measured using the Promega Bright-Glo luciferase assay system. Values are given as arbitrary units standardized to 100 copies of the luciferase gene per cell. For each reporter construct, 4 to 6 independent pools were tested, and the average values ± SD are presented.

Quantitative PCR. Real-time reverse transcription-PCR (RT-PCR) was performed as described previously (14). Logarithmically growing *D. discoideum* cells were washed in 17 mM phosphate buffer (pH 6.2) and stored as pellets of 2 × 10⁷ cells at –80°C until further use. Total RNA was prepared from frozen cells by use of a Qiagen RNeasy Mini kit according to the provided manual. cDNA was synthesized by reverse transcription of 500 ng of total RNA, using an oligodeoxythymidine primer and a Qiagen Omniscript RT kit. Real-time PCR signals

were standardized for expression of the gene encoding glyceraldehyde-3-phosphate dehydrogenase (GAPDH) (*gpdA*; Dictybase entry DDB0185087) (8). The *gpdA* gene was amplified with primers *gpdA*-01 and *gpdA*-02, yielding a 247-bp PCR product from genomic DNA and a 156-bp fragment from cDNA. Thus, amplification of *gpdA* was also suitable for determining genomic DNA contamination in cDNA preparations by conventional RT-PCR prior to real-time RT-PCR runs. Real-time amplification was carried out using Stratagene Brilliant SYBR green QPCR master mix on a Stratagene Mx3000P instrument. Differential expression was calculated by the method of Pfaffl (21), using GAPDH as a reference. Results for three biological replicates are indicated (mean ± SD). TRE5-A transcript levels were determined with primers specific for the ORF1 sequence (Rep-108, 5'-GTCATAAACATCAATCCGAACACAGAC-3'; and Rep-109, 5'-GTTAGATTGTCTAGTTCAATGATAGTGTC-3'). Expression of genes encoding RNA-dependent RNA polymerases was determined using the following primers: *rrpA*-01, 5'-GAACGTCAGAAGCTTGGTAAATTGTATC A-3'; *rrpA*-02, 5'-TAACCTACAGTTTGTAAACCGAATGTTTAC-3'; *rrpB*-01, 5'-GAACGTCAGAAGCTTGGTAAATGTATAA-3'; *rrpB*-02, 5'-GTGGAT AACCTTTAGTTTAAACCAAAC-3'; *rrpC*-01, 5'-GGTGTGTTTATAGTAAAA AAGAATCATTC-3'; and *rrpC*-02, 5'-CAACTATCCAAGAATTTATGAACA TTTAC-3'.

Northern blots. Agarose gel electrophoresis and blotting of total RNA were performed as described previously (27). Strand-specific DNA probes to detect TRE5-A (+) RNA and (–) RNA were prepared by cloning the BglII restriction fragment covering nucleotide positions 4610 to 5604 of TRE5-A.1 from plasmid pB3 (18) into pGEM7Zf(–) (Promega). Strand-specific radiolabeling of TRE5-A RNA was then achieved by primer extension in the presence of [α -³²P]dATP, using a *Taq* Cyclist DNA sequencing kit from Stratagene (27), with vector-specific primers at both ends of the cloned insert.

RESULTS

Accumulation of TRE5-A transcripts in *D. discoideum* cells requires CbfA. Although CbfA is required to regulate the expression of a multitude of genes in the *D. discoideum* genome (14), its original isolation as a C-module-binding factor suggested an additional role for the factor in the regulation of TRE5-A transcript levels and/or retrotransposition activity. To evaluate whether CbfA has an influence on the steady-state transcript levels of TRE5-A, we conducted quantitative RT-PCR on poly(dT)-primed cDNA preparations. Considering that retrotransposon activity is a source of genome instability, we expected that the function of CbfA might be to suppress the accumulation of high levels of TRE5-A transcripts, the prerequisite for retrotransposition. To our surprise, we observed that the depletion of CbfA from *D. discoideum* cells in the mutant strain JH.D did not lead to stabilization, but rather to a loss of TRE5-A transcripts. A reduction in TRE5-A expression was determined, by a factor of 5.3 ± 1.5 (*n* = 7), compared with that of the parent strain AX2.

To evaluate whether the accumulation of both (+) RNA and (–) RNA TRE5-A transcripts was affected in CbfA-depleted cells, we prepared Northern blots of total RNA from *D. discoideum* cells and used strand-specifically radiolabeled DNA probes to visualize (+) RNA and (–) RNA. To increase the sensitivity of the assay, we treated cells in parallel cultures with the respiratory chain blocker antimycin A, which is known to increase the amount of TRE5-A transcripts in growing *D. discoideum* cells (22). As shown in Fig. 1, the levels of both (+) RNA and (–) RNA were drastically reduced in the absence of a functional CbfA protein.

To determine if the observed loss of TRE5-A transcripts in the CbfA mutant was in fact related to the depletion of CbfA, we performed complementation studies using two plasmid-borne CbfA variants. The first was a nearly full-length CbfA²⁻⁹⁹⁸ protein expressed from the strong *act15* promoter.

FIG. 1. CbfA is involved in regulation of TRE5-A steady-state RNA levels. AX2 and JH.D cells were grown to late logarithmic phase in the absence or presence of 80 μ M antimycin A as described previously (22). Total RNA was prepared, separated by agarose gel electrophoresis, and blotted. The filter was first hybridized with a (-) RNA strand-specific probe, then stripped and hybridized with a (+) RNA strand-specific TRE5-A DNA probe, and finally stripped again and hybridized to histone H3 (*hstC*) RNA as a loading control. Size markers to the left refer to the migration positions of 26S and 17S rRNAs (ca. 4.1 and 1.9 kb, respectively).

The CbfA²⁻⁹⁹⁸ protein proved to be functional in restoring the aggregation phenotype of JH.D cells (27). The second was the carboxy-terminal domain of CbfA (CbfA⁷²⁴⁻⁹⁹⁸; CbfA-CTD), also expressed from the *act15* promoter, which is known to act as an independent gene regulatory entity for about half of all CbfA-regulated genes (14). When either full-length CbfA or CbfA-CTD was produced in the JH.D background, complete reversion of both TRE5-A (+) RNA and (-) RNA expression was observed (Fig. 2).

A possible explanation for the simultaneous loss of TRE5-A (+) RNA and (-) RNA in the CbfA mutant could be direct positive regulation of the two responsible TRE5-A promoters, the A module and the C module, by CbfA. To test this possibility, we inserted the A module and the C module upstream of a luciferase reporter gene in a *D. discoideum* expression vector. AX2 and JH.D cells were transformed with these vectors, and luciferase reporter gene activity was determined. Both promoters mediated expression of luciferase, with reporter activity above the background, but we did not observe significant differences in A-module or C-module promoter activity in the CbfA-depleted mutant JH.D cells in comparison to AX2 cells (Fig. 3).

CbfA increases TRE5-A retrotransposition activity in *D. discoideum* cells. The results described above indicate that CbfA is a host factor for TRE5-A expression in growing *D. discoideum* cells. We wanted to determine whether CbfA increased not only the steady-state levels of TRE5-A-derived transcripts but also the retrotransposition frequency of the element. First, we measured the frequency of *de novo* TRE5-A retrotransposition events in the CbfA-depleted mutant strain JH.D, using the previously established “TRE trap” assay. This

FIG. 2. Ectopic expression of CbfA in a CbfA-depleted mutant rescues TRE5-A expression. A Northern blot was prepared with total RNAs from the indicated strains: lane 1, AX2 cells; lane 2, untransformed JH.D cells; lane 3, JH.D cells transformed with empty expression vector; lane 4, JH.D cells expressing CbfA-CTD; and lane 5, JH.D cells expressing full-length CbfA. The filter was hybridized successively with (-) RNA strand-specific and (+) RNA strand-specific TRE5-A DNA probes, followed by a probe detecting histone H3 (*hstC*) RNA as a loading control. Size markers to the left refer to the migration positions of 26S and 17S rRNAs (ca. 4.1 and 1.9 kb, respectively).

assay reliably reflects the natural retrotransposition activity of the TRE5-A population in the *D. discoideum* genome (2, 23). Briefly, the TRE trap assay consists of a cloned *D. discoideum* UMP synthase gene (*pyr5-6*) that contains an artificial intron (Fig. 4). Into this intron, we placed a tRNA gene that served as a target for integration of TRE5-A elements, thus disrupting the entire *pyr5-6* gene. When such a TRE^{trap} gene was transformed into the *ura*⁻ *D. discoideum* strain DH1, the TRE^{trap} plasmid readily complemented the *ura*⁻ phenotype and converted the cells to a *ura*⁺ phenotype. Such cells, however, were

FIG. 3. Activities of the A module and the C module in the CbfA mutant strain JH.D. AX2 and JH.D cells were transformed with plasmid pGEM-A-luc (gray bars) or pGEM-C-luc (black bars) and with pISAR. After G418 selection, clones were pooled, and the average copy numbers of the expression plasmids were determined by quantitative PCR. Only pools with average plasmid copy numbers between 25 and 80 were selected for luciferase reporter assays. The values resulted from 4 to 6 pools per transformation and were normalized for 100 plasmid copies. Background activities of AX2 cells and JH.D cells transformed only with pISAR were 9 ± 10 and 17 ± 17 arbitrary units, respectively.

FIG. 4. Outline of the TRE trap assay.

sensitive to the cytostatic drug 5-FOA and were killed unless they acquired mutations in the TRE^{trap} gene. Under selection with 5-FOA and uracil, resistant ura⁻ clones appeared as a consequence of the disruption of the TRE^{trap} gene by the *de novo* integration of endogenous active TRE5-A elements (Fig. 5). As a negative control, we used a TRE^{trap} plasmid that lacked the bait tRNA gene. Under these conditions, the TRE trap bait did not attract TRE5-A retrotransposons; only a few clones were obtained (Fig. 5), and these probably arose from spontaneous mutations of the TRE^{trap} gene rather than targeted integration of TRE5-A elements (data not shown; discussed in reference 2).

We developed ura⁻ mutants in CbfA-depleted JH.D cells by prolonged selection of cells in the presence of 5-FOA and uracil. For further experiments, we chose a JH.D[ura⁻] mutant that had a complete chromosomal deletion of the *pyr5-6* coding region, as determined by PCR analysis (data not shown). We transformed TRE^{trap} plasmids into the JH.D[ura⁻] cells and subjected JH.D[ura⁺/TRE^{trap}] transformants to 5-FOA selection. As shown in Fig. 5, CbfA depletion of *D. discoideum* cells resulted in a >90% reduction in TRE5-A retrotransposition activity. We noticed a reproducible increase in background ura⁻ clones obtained from JH.D[ura⁺/TRE^{trap}] transformants after 5-FOA selection compared to those obtained from DH1[ura⁺/TRE^{trap}] cells in the absence of a target tRNA gene (Fig. 5). This increase may reflect a generally higher mutation rate in CbfA-depleted cells, but this was not analyzed further.

Although these data were promising, they were challenged by the different strain histories of the cells used in this experiment: whereas the ura⁻ mutant DH1 (the wild-type strain in this experiment) was derived from the axenic *D. discoideum* strain AX3, our CbfA mutant strain (JH.D) was derived from AX2. Although AX3 and AX2 have the same parent strain, NC4, the different laboratory histories of both strains may have corrupted TRE5-A retrotransposition activity in AX2 cells,

FIG. 5. TRE5-A retrotransposition activity in JH.D cells. TRE^{trap} plasmids without a tRNA gene as an integration target (gray bars) or with a *D. discoideum* Val^{UAC} tRNA gene as bait to attract integration of mobile TREs (black bars) were transformed into DH1[ura⁻] or JH.D[ura⁻] cells. Mean clone numbers (\pm SD) from 5 petri dishes are shown.

thus mimicking a CbfA effect on TRE5-A retrotransposition in JH.D cells. We therefore decided to perform complementation studies in JH.D[ura⁻] cells expressing plasmid-borne CbfA to rescue the aberrant TRE5-A retrotransposition activities. In two parallel series of transformations, TRE^{trap} plasmids that either contained or lacked a target tRNA gene were introduced into JH.D[ura⁻] cells. The resulting transformants were supertransformed with plasmids that conferred resistance to G418 and supported the expression of CbfA²⁻⁹⁹⁸ or CbfA-CTD. First, stable transformants were screened for comparable expression of the plasmid-borne CbfA variants (data not shown). Next, we measured the relative expression levels of TRE5-A in the transformants by quantitative RT-PCR (Fig. 6A). As expected from our data described above, we found that the expression of CbfA²⁻⁹⁹⁸ or CbfA-CTD increased the expression of TRE5-A in cells carrying the TRE^{trap} gene. Finally, we measured the retrotransposition activity of the TRE5-A population in the TRE trap assay. The natural mutation rate observed for the TRE^{trap} gene was approximately 45 clones per 10⁷ cells (Fig. 6B). This rate was not increased by the ectopic expression of CbfA²⁻⁹⁹⁸ or CbfA-CTD (Fig. 6B). In contrast, when a target tRNA gene was included in the TRE^{trap} gene, the mutation rate at the TRE^{trap} gene increased approximately 4-fold in the presence of full-length CbfA, to roughly the wild-type levels observed in DH1 cells. This observation indicated full rescue of retrotransposition activity of the TRE5-A population. Unexpectedly, we found that expression of CbfA-CTD, although fully restoring aberrant TRE5-A expression, did not rescue the retrotransposition deficiency of the CbfA mutant. This result was observed in three independent experiments, and the reason for it remains obscure.

DISCUSSION

CbfA is a host factor that supports TRE5-A expression. In this report, we describe experiments demonstrating that CbfA is a host factor for TRE5-A expression in growing *D. discoideum* cells. In contrast to our prediction, we found that CbfA does not act as a component of the cellular defense machinery that is expected to limit the expression and subsequent ampli-

FIG. 6. Complementation of TRE5-A retrotransposition in the CbfA mutant. (A) TRE5-A.1 expression was quantified in JH.D[TRE^{trap}/ura⁺] transformants by real-time RT-PCR. Expression of TRE5-A in AX2 cells versus untransformed JH.D[ura⁻] cells served as a control (white bar, column 1). JH.D[ura⁻] cells were transformed with TRE^{trap} plasmids without a tRNA gene as an integration target (gray bars, columns 2 to 4) or with a *D. discoideum* Val^{UAC} tRNA gene as bait to attract mobile TREs (black bars, columns 5 to 7). Resulting JH.D[TRE^{trap}/ura⁺] cells were then supertransformed with empty expression vector (columns 2 and 5) or with plasmids that allowed for the expression of either CbfA-CTD (columns 3 and 6) or full-length CbfA (columns 4 and 7) in the JH.D background. All expression data were obtained from 4 to 8 independent transformants and are given relative to untransformed JH.D[ura⁻] cells, meaning that values of >1 indicate more TRE5-A expression in the transformants or AX2 cells than in untransformed JH.D[ura⁻] cells. (B) JH.D[TRE^{trap}/ura⁺] cells were subjected to selection in 5-FOA and uracil. Numbers of 5-FOA-resistant clones were calculated for 5 petri dishes and are given as means \pm SD. Columns are the same as in panel A. The experiment was repeated twice with similar results.

fication of retrotransposons in order to maintain genome integrity. CbfA has a strong supportive effect on the expression of both (+) RNA and (-) RNA of TRE5-A, but we found no pronounced differences in the promoter activity of the A module or the C module in CbfA-depleted cells, despite the sharp decrease in steady-state transcript levels of TRE5-A RNA in the mutant.

The data suggest that CbfA influences TRE5-A expression indirectly. An attractive hypothesis is that steady-state levels of TRE5-A RNA are regulated by posttranscriptional gene silencing (PTGS). Interestingly, we observed that the exposure of cells to antimycin A, and also the presence of a functional CbfA protein, stabilized both (+) RNA and (-) RNA of

TRE5-A. In some organisms, for example, *Drosophila*, RNA interference (RNAi) is strictly ATP dependent (30), while in other organisms, such as humans (as demonstrated with human cells), RNAi seems to function in an ATP-independent manner (31). For *D. discoideum*, it is postulated that all known PTGS effects are mediated by RNA-dependent RNA polymerases (20), meaning that PTGS requires highly energy-consuming RNA-amplifying steps to work. Thus, assuming that antimycin A limits the energy metabolism in *D. discoideum* cells by blocking respiratory chain function, one could argue that antimycin affects TRE5-A transcript levels by blocking PTGS mechanisms. The role of CbfA in the stabilization of (+) RNA and (-) RNA of TRE5-A remains elusive. We speculate that CbfA regulates the expression of a gene involved in PTGS. This question will be addressed in future studies.

CbfA is essential for TRE5-A retrotransposition. Although CbfA-CTD is required and sufficient to maintain high TRE5-A transcript levels in *D. discoideum* cells, it was not able to restore the diminished retrotransposition of TRE5-A in the CbfA mutant. This result suggested a role for CbfA in the retrotransposition process in addition to the regulation of TRE5-A expression. Is CbfA a component of the TRE5-A preintegration complex? All available data indicate that TRE5-A is a canonical non-LTR retrotransposon that integrates via target-primed reverse transcription (TPRT), which means that no free double-stranded DNA intermediates of TRE5-A are supposed to occur in the cell to which CbfA may bind through its DNA-binding capacity. It also seems improbable that CbfA binds to TRE5-A-derived RNA because CbfA does not contain predictable RNA-binding domains or possess other enzymatic functions presumably required for the reverse transcription and integration processes. Although productive integration of mobilized retrotransposons may rely on the activity of host factors such as DNA repair enzymes, the reverse transcription and integration of such elements are likely to be mediated exclusively by TRE5-A ORF1/ORF2 functions. We concluded that it is unlikely that host-encoded CbfA has a direct function in the TPRT process.

Instead, the retrotransposition frequency of TRE5-A may be affected indirectly by CbfA if a component of the cellular DNA repair machinery exists that is expressed in a CbfA-dependent manner and cannot be controlled by CbfA-CTD alone. Support for this assumption may be deduced from the observation that we reproducibly obtained more ura⁻ mutants in the TRE trap assay with JH.D cells than in that with DH1 wild-type cells in the absence of a tRNA gene (columns 1 and 3 in Fig. 5), a sign of an increased general mutation rate in the mutant. However, we assume that nonproductive attempts by TRE5-A to integrate upstream of the bait tRNA gene in the TRE trap assay may have caused substantial genome instability at this locus due to insufficient DNA repair and, in turn, should have generated excess ura⁻ mutants. However, excess ura⁻ mutants were not observed for the CbfA mutant (column 4 in Fig. 5). On the contrary, we found that retrotransposon-induced mutagenesis of the TRE^{trap} gene was almost completely lost in the absence of CbfA.

One could imagine that the normal cellular function of CbfA as a putative chromatin-remodeling enzyme may provide a chromatin architecture in the vicinity of tRNA genes that sup-

ports the integration process. This is speculative as long as the putative functions of the JmjC and zinc finger domains of CbfA remain elusive.

In conclusion, CbfA is a host-encoded factor that strongly supports TRE5-A amplification in modern *D. discoideum* strains by controlling the absolute amount of transcript that is available for translation of TRE5-A proteins, reverse transcription of TRE5-A (+) RNA, and subsequent integration into chromosomal loci. CbfA has two distinct, indirect functions that can be assigned to different parts of the protein: maintenance of high steady-state levels of TRE5-A transcripts requires only the carboxy-terminal domain of CbfA, whereas the remaining parts of the protein, perhaps utilizing chromatin-remodeling activity of CbfA, are required to pass through a complete retrotransposition cycle.

ACKNOWLEDGMENTS

We are grateful to W. Nellen for providing the *rrp4* to *-C* mutants. This work was supported by the German Research Foundation DFG (WI 1142/6-1).

C-module-binding factor A (Cbfa) is a jumonji-type transcription regulator that is important for maintaining the expression and mobility of the retrotransposable element TRE5-A in the social amoeba *Dictyostelium discoideum*. Cbfa-deficient cells have lost TRE5-A retrotransposition, are impaired in the ability to feed on bacteria, and do not enter multicellular development because of a block in cell aggregation. In this study, we performed Illumina RNA-seq of growing Cbfa mutant cells to obtain a list of Cbfa-regulated genes. We demonstrate that the carboxy-terminal domain of Cbfa alone is sufficient to mediate most Cbfa-dependent gene expression. The carboxy-terminal domain of Cbfa from the distantly related social amoeba *Polysphondylium pallidum* restored the expression of Cbfa-dependent genes in the *D. discoideum* Cbfa mutant, indicating a deep conservation in the gene regulatory function of this domain in the dictyostelid clade. The Cbfa-like protein Cbfb displays ~25% sequence identity with Cbfa in the amino-terminal region, which contains a JmjC domain and two zinc finger regions and is thought to mediate chromatin-remodeling activity. In contrast to Cbfa proteins, where the carboxy-terminal domains are strictly conserved in all dictyostelids, Cbfb proteins have completely unrelated carboxy-terminal domains. Outside the dictyostelid clade, Cbfa-like proteins with the Cbfa-archetypical JmjC/zinc finger arrangement and individual carboxy-terminal domains are prominent in filamentous fungi but are not found in yeasts, plants, and metazoans. Our data suggest that two functional regions of the Cbfa-like proteins evolved at different rates to allow the occurrence of species-specific adaptation processes during genome evolution.

Cells of the social amoebae (dictyostelids) live in the soil and feed on bacteria. Under unfavorable conditions, dictyostelid cells can aggregate and form multicellular fruiting bodies that hold dormant spores to ensure the survival of the species (1, 2). Insight into the genome structures of related dictyostelids has revealed an unexpected degree of genome flexibility and genetic diversity, suggesting that the study of these organisms may be valuable in understanding the evolutionary forces that drive genomic adaptation processes (3–5).

The model species *Dictyostelium discoideum* has an unusual genome, where only ~22% of the nucleotides are GC and 65% of the DNA codes for proteins (3). Compared with other dictyostelid genomes that present similar gene-dense environments (4), the *D. discoideum* genome harbors a surprisingly high percentage of mobile genetic elements (6). Transposon activity can be disastrous for the host if it leads to insertional mutagenesis, nonallelic homologous recombination, or induction of chromosome breaks (7, 8). Therefore, the activity of these parasitic elements must be carefully controlled by the host to maintain genome stability. *D. discoideum* has emerged as an excellent model to study the interactions between transposable elements and compact host genomes (9).

The retrotransposon TRE5-A is characterized by three outstanding features: an active population of elements in the *D. discoideum* genome is maintained (10), gene disruption rarely occurs because integration is targeted to the vicinity of tRNA genes (11), and a considerable amount of minus strand (“antisense”) RNA is produced from a promoter located at the 3′ end of the element, the C module (12, 13). The large amount of minus strand RNA in growing *D. discoideum* cells suggests that TRE5-A retrotransposition may be regulated by posttranscriptional silencing. The C-module-binding factor A (Cbfa) was discovered in a search for cellular factors that bind to the C module *in vitro* and may mod-

ulate TRE5-A amplification by regulating the TRE5-A minus strand of RNA (14).

Attempts to delete Cbfa from *D. discoideum* cells by gene replacement have been unsuccessful. As an alternative, a *cbfa* gene knock-in mutant was generated in which the codon at position 455 was replaced with a TAG (*amber*) stop codon (15). Because of the low frequency of *amber* codons in the *D. discoideum* genome, the expression of an *amber* suppressor tRNA gene does not produce a phenotype (16) but rather allows readthrough translation of the full-length protein from the *cbfa* (*amber*) mRNA. Because of the low efficacy of *amber* suppression, the JH.D strain produces less than 5% of the full-length Cbfa protein (15).

In cells of the Cbfa mutant JH.D, both plus- and minus-strand RNA from the retrotransposon TRE5-A is diminished and the mobility of the endogenous retrotransposon population is drastically reduced (13). Thus, Cbfa is a positive regulator of TRE5-A amplification. Expression and retrotransposition of TRE5-A can be restored in JH.D cells by the ectopic expression of the full-length Cbfa protein. Interestingly, the expression of the isolated carboxy-terminal domain (CTD) of Cbfa in the mutant cells was sufficient for complete restoration of the TRE5-A transcript levels, even though TRE5-A retrotransposition was unaffected (13).

JH.D cells are defective in phagocytosis, cytokinesis (15), and multicellular development (17). In mutant cells, the expression of the aggregation-specific adenyl cyclase ACA is strongly reduced; therefore, cyclic-AMP (cAMP)-induced gene expression is absent. However, multicellular development of JH.D cells can be restored either by the application of exogenous cAMP pulses or by mixing mutant and wild-type cells, suggesting that the developmental phenotype of JH.D cells is not cell autonomous (17). The aggregation block in JH.D cells can be overcome by the ectopic expression of the full-length CbfA protein (17), but not by the expression of the isolated CbfA CTD (18).

The observation that the CTD of CbfA restored TRE5-A expression raised questions concerning the origin of this domain and its role as an independent gene regulatory entity in CbfA function. In this study, we show that CbfA is a general transcriptional regulator in growing *D. discoideum* cells and that most CbfA-dependent gene expression is mediated by the CbfA CTD. The CbfA protein, including the CTD, is highly conserved throughout dictyostelid evolution. Dictyostelids contain a CbfB protein. This protein is paralogous to CbfA in the amino-terminal portion of the protein but has an individual CTD with no similarity to those of other CbfA or CbfB proteins. We speculate that the two gene regulatory elements within the CbfB proteins in individual species have evolved differently to facilitate the emergence of genome-specific gene regulatory functions.

MATERIALS AND METHODS

Dictyostelids. The dictyostelid species used in this study were obtained from the Dictyostelium Stock Center, which can be accessed at dictyBase (<http://dictybase.org>). The following strains were used (dictyBase strain identification numbers are in parentheses): *D. citrinum* OH594 (DBS0235738), *D. rosarium* M45 (DBS0235885), *D. dimorphaformum* AR5B (DBS0235745), *D. giganteum* WS589 (DBS0235820), *D. sphaerocephalum* GR11 (DBS0235889), *D. robustum* Ch53 (DBS0235883), *D. firmibasis* TNS-C-14 (DBS0235812), *D. intermediatum* PJ11 (DBS0235829), *D. longosporum* TNS-C-109 (DBS0235836), *D. clavatum* TNS-C-189 (DBS0235739), *D. brunneum* WS700 holotype (DBS0235734), *D. breifeldianum* G-12-1 (DBS0235732), *D. minutum* 71 (DBS0235843), *D. lacteum* (DBS0235831), *Polysphondylium pallidum* WS320 (ATCC 44843), *Acytostelium subglobosum* Lb1 (DBS0235452), and *D. fasciculatum* SH3 (DBS0235810).

Isolation of the dictyostelid *cbfA* and *cbfB* gene sequences. The dictyostelid species were grown on SM/5 agar plates (19) in association with *Raoultella planticola*. Before the first multicellular stages appeared, the cells were harvested, washed, and stored as pellets consisting of 2×10^7 cells. The pellets were frozen at -80°C . Genomic DNA was prepared from the frozen cells with the Qiagen DNeasy Tissue kit. Total RNA was prepared from the frozen cells with the Qiagen RNeasy Minikit. cDNA synthesis was performed with the Qiagen Omniscript RT kit with an oligonucleotide-deoxythymidine primer.

Degenerate primers were derived from the *D. discoideum* CbfA protein sequence and multiple sequence alignments of CbfA sequences from group 4 species. DNA sequences of the orthologous *cbfA* genes were generated from overlapping PCR fragments. The PCR products were either cloned into the pGEM-T plasmid (Promega) or sequenced directly from the PCR fragments. The DNA sequences representing approximately 90% of the encoded CbfA proteins were assembled and aligned with COBALT (20).

The *D. discoideum* *cbfA* and *cbfB* gene sequences can be accessed via dictyBase (<http://dictybase.org>) under accession numbers DDB_G0279409 and DDB_G0293470, respectively.

Information about the *cbfA* and *cbfB* genes of *D. fasciculatum* and *P. pallidum* was assembled in the Social Amoebas Comparative Genome Browser (<http://sacgb.fli-leibniz.de/cgi/index.pl>) from the preliminary

data of the comparative genome sequencing project (4). CbfA and CbfB sequences of *A. subglobosum* were generously provided by the *Acytostelium* gene analysis team at the University of Tsukuba (H. Urushihara, personal communication). The *cbfA* and *cbfB* sequences from *D. purpureum* were generously provided by A. Kuspa (Baylor College of Medicine, Houston, TX). These sequences are now publicly available at dictyBase (5). The structures of the *cbfA* and *cbfB* gene sequences as predicted by the dictyostelid comparative genome projects were confirmed by sequencing overlapping PCR products that were generated from both genomic DNA and cDNA of the respective species.

Expression of the CbfA CTD mutant proteins. A gene fragment spanning amino acids 724 to 1000 of the *D. discoideum* CbfA protein was cloned as a BamHI fragment into the pDXA-GFP2 plasmid (21). The resulting plasmid, pDXA-DdCbfA-CTD, was later transformed into JH.D cells (15). The corresponding sequence of *P. pallidum* CbfA was isolated by PCR and cloned as mentioned above. All of the strains were cultured in standard HL-5 medium (ForMedium, Norfolk, United Kingdom) supplemented with 10 $\mu\text{g}/\text{ml}$ G418. Live cells expressing the green fluorescent protein (GFP)-tagged CbfA CTD were stained with 20 $\mu\text{g}/\text{ml}$ 4',6-diamidino-2-phenylindole (DAPI) in phosphate-buffered saline (PBS) for 30 min at room temperature. The cells were washed with PBS and observed with an Axio Observer Z1 microscope (Carl Zeiss AG). The expression of GFP-tagged CbfA CTD proteins was analyzed by Western blotting as described previously (22).

Illumina RNA sequencing (RNA-seq). Total RNA was prepared from cells grown in three independent cultures containing AX2 cells (wild type), JH.D cells (the CbfA-underexpressing mutant), or JH.D cells expressing the GFP-tagged CbfA CTD from *D. discoideum* or *P. pallidum*. For library preparation, 5 μg of total RNA per sample was processed with an Illumina mRNA-Seq sample prep kit (RS-122-2001) by following the manufacturer's instructions. Library preparation was performed with the total RNA from the three independent cultures. The libraries were sequenced with a HiSeq 2000 instrument in a single-read approach with 50 cycles resulting in reads with a length of 50 nucleotides. Reads were mapped to the *D. discoideum* reference genome downloaded from dictyBase (<http://dictybase.org>) with the Illumina-supplied tool ELAND (23) by using standard parameters. The expression values were calculated by determining the number of uniquely mappable reads per transcript and normalizing that value to the total number of mappable reads and the length of the respective transcript (adapted from reference 24). This approach resulted in RPKM values (reads per kilobase transcript and million mappable reads) representing the expression level of the respective transcript. The determination of differentially expressed genes was performed with the unnormalized count data with the R statistical computing (25) tools edgeR (26) and DESeq (27). Genes were considered to be differentially expressed if the *P* value was ≤ 0.01 . Furthermore, an at least 3-fold difference in gene expression was considered CbfA-dependent regulation. Gene ontology (GO) term enrichment analyses were performed with AmiGO version 1.8 (28).

Phylogenetic analysis. The multiple-sequence alignment was performed with ClustalX 2.0 (29). The phylogenetic tree was generated with Tree-Puzzle 5.2 (30) under the Dayhoff model. The heterogeneity rate was uniform. Supporting values are derived from 1,000 puzzling steps. The tree was rooted with the *Naegleria* sequence as the outgroup.

Quantitative reverse transcription (qRT)-PCR. Total RNA was prepared from frozen pellets consisting of 2×10^7 cells with the Qiagen RNeasy Minikit according to the protocol provided. cDNA was synthesized by the RT of 500 ng of total RNA with an oligo(dT) primer and the Qiagen Omniscript RT kit. Real-time amplification of the genes was performed with the *Taq* polymerase mix from Jena Bioscience (Jena, Germany) supplemented with EvaGreen Fluorescent Gel Stain and ROX Reference Dye (both from Jena Bioscience, Jena, Germany) on a Stratagene Mx3000P instrument. The sequences of the primers used are listed in Table S1 in the supplemental material. All of the measurements were performed in triplicate. Real-time PCR signals were normalized to the

FIG 1 Transcriptome analysis of CbfA mutant JH.D cells. Shown are the results from an RNA-seq experiment with AX2 and JH.D cells. The reads were mapped to 12,317 gene models, and read counts were standardized to transcript lengths and 1 million reads (RPKM values). The mean RPKM values of three independent cultures are plotted as gray symbols. The black symbols highlight genes that were reported to show statistically significant differential levels of regulation ($P \leq 0.01$) of at least 3-fold.

expression of the gene encoding *catA* (dictyBase entry DDB_G0274595). After an initial denaturing step at 95°C for 10 min, PCR was performed for 40 cycles at 95°C for 30 s, 60°C for 45 s and 72°C for 30 s. Differential gene expression was calculated according to the Pfaffl method (31) with *catA* as a reference gene.

Nucleotide sequence and RNA-seq data accession numbers. The partial *cbfA* gene sequences that were determined in this study have been deposited in GenBank under accession numbers JQ918362 (*D. giganteum cbfA*), JQ918358 (*D. citrinum cbfA*), JQ918363 (*D. intermedium cbfA*), JQ918366 (*D. sphaerocephalum cbfA*), JQ918359 (*D. clavatum cbfA*), JQ918360 (*D. dimigraformum cbfA*), JQ918361 (*D. firmibasis cbfA*), JQ918365 (*D. rosarium cbfA*), JQ918357 (*D. brunneum cbfA*), and JQ918356 (*D. brefeldianum cbfA*). The RNA-seq data have been deposited in the Gene Expression Omnibus database under accession number GSE38418.

RESULTS

CbfA is a general transcriptional regulator. The complex phenotype of CbfA-deficient mutants suggested that CbfA functions as a general transcriptional regulator in growing and developing *D. discoideum* cells. To test this hypothesis, we defined a list of CbfA-dependent genes in growing cells. To this end, we performed Illumina RNA-seq analyses on the *D. discoideum* wild-type strain AX2 and the CbfA-deficient mutant JH.D. RNA-seq on three independent cultures from each strain was highly reproducible (see Fig. S1 in the supplemental material) and yielded approximately 20 million sequence reads per RNA preparation, which were mapped to 12,317 *D. discoideum* gene models. We plotted the normalized sequence reads (RPKM values) for AX2 versus JH.D. Considerable differences in gene expression between the strains existed (Fig. 1). Statistical analysis revealed that 2,298 genes were differentially expressed between the AX2 and JH.D samples. As expected, the numbers of differentially expressed genes varied considerably, depending on the threshold setting (see Fig. S2 in the

FIG 2 qRT-PCR analysis of a representative set of CbfA-regulated genes. Comparison of RNA-seq data (gray bars) with qRT-PCR data (black bars) for five CbfA-repressed and five CbfA-supported genes. The qRT-PCR was performed with cDNA prepared from three independent cultures of AX2 and JH.D cells that were different from the three cultures used for RNA-seq. Values are presented as means of three biological replicates \pm the standard deviations. Note that the expression of genes is calculated for JH.D versus AX2 cells, meaning that values of >1 represent genes usually repressed by CbfA (and therefore overexpressed in JH.D), whereas values of <1 represent genes whose expression is supported by CbfA.

supplemental material). A 3-fold change in gene expression was considered to be indicative of CbfA-regulated gene expression. With this threshold, 1,030 genes were differentially regulated (see Table S2 in the supplemental material). Of these genes, 584 had reduced expression in JH.D cells, suggesting that these genes are positively regulated by CbfA. Fifty-seven genes were downregulated more than 20-fold in the mutant. The most pronounced CbfA-regulated gene was *abpF* (205-fold differential expression), which codes for an actin-binding protein that is most likely localized to the centrosomes. We found that 446 genes were upregulated in JH.D cells, which suggests that CbfA normally represses these genes. Eighty-six genes were upregulated by at least 20-fold in the CbfA mutant cells versus the AX2 cells. The most significant differences were a 458-fold change in the expression of a gene with unknown function (DDB_G0283511) and a 388-fold upregulation of *cyp513F1*, which encodes a cytochrome P450 enzyme. The gene *agnC*, which codes for an Argonaute protein that may be involved in processes involving posttranscriptional gene silencing, was upregulated by 225-fold in the CbfA mutant cells. We performed a qRT-PCR analysis of a representative set of 10 CbfA-regulated genes to verify the RNA-seq data. We measured the gene expression in the RNA preparations from 3 cultures that were grown independently from the cells used for RNA-seq. As indicated in Fig. 2, the qRT-PCR data confirmed the RNA-seq results.

GO term enrichment analysis with the program AmiGO set at a $P < 0.05$ cutoff indicated that a significant enrichment of the positively CbfA-regulated genes was involved in the assembly and maintenance of the actomyosin cytoskeleton and phagocytic vesicles, as well as general cellular processes, such as cytokinesis and cell morphogenesis (see Table S3 in the supplemental material). This observation correlated well with the growth characteristics of CbfA-deficient cells, including a decreased phagocytosis rate, slow growth on bacteria, and the generation of giant cells containing

FIG 3 Phylogenetic relationships of Cbfa-like proteins. Protein sequences corresponding to amino acids 1 to 553 of *D. discoideum* Cbfa (JmjC/ZF region) were aligned with ClustalX 2.0 and analyzed with Tree-Puzzle 5.2. The values above the lines indicate the support values derived from 1,000 puzzling steps. In addition to the dictyostelid Cbfa and Cbfb proteins, the following fungal Cbfa-like proteins were used in this alignment: *Aspergillus nidulans* (GI: 67528200), *Chaetomium globosum* (GI: 116199707), *Coccidioides immitis* (GI: 119188365), *Gibberella zeae* (GI: 46138433), *Magnaporthe grisea* (GI: 39973571), *Neosartorya fischeri* (GI: 119501326), *Neurospora crassa* (GI: 85078924), and *Phaeosphaeria nodorum* (GI: 111066574). Note that the *N. crassa* protein is identical to DMM-1, as reported by Honda et al. (39). The ZF2 region was also aligned with the zinc finger domain of *Arabidopsis* monoamine oxidase A repressor R1 (GI: 145360248) and a related zinc finger region in human cell division cycle-associated 7-like protein isoform 2 (GI: 188497635). Domain structures are schematically presented for *D. discoideum* Cbfa, *D. discoideum* Cbfb, and *N. crassa* DMM-1. JmjC, jumonji C domain; ZF, zinc finger region, AT, AT hook.

multiple nuclei (15). We performed a qRT-PCR analysis of 10 of these genes on RNA from three independently grown cultures to confirm the RNA-seq data. The genes selected exhibited between 3.3- and 31.2-fold higher expression levels in wild-type cells than in the Cbfa mutant cells in the RNA-seq experiment. Surprisingly, the qRT-PCR data did not confirm the RNA-seq data (data not shown). This discrepancy, however, was not due to a general incongruence between RNA-seq and qRT-PCR data because the values for the genes measured by qRT-PCR in the RNA samples that we used for RNA-seq were comparable to the values measured by RNA-seq (not shown). Thus, it is probable that the expression of the genes putatively involved in the Cbfa-dependent regulation of phagocytosis is generally variable and subject to subtle changes in culture conditions and the involvement of Cbfa in this gene regulation remains uncertain. We should note, however, that the slow-growth phenotype of JH.D cells on bacteria lawns is reversed by the expression of Cbfa in the mutant (data not shown).

Cbfa is a highly conserved protein. *D. discoideum* Cbfa is a 1,000-amino-acid multidomain protein (Fig. 3) that belongs to the family of jumonji-type transcriptional regulators. These proteins are often involved in deciphering the histone code by removing methyl groups from methyllysine or methylarginine residues in the histone tails (32, 33). A “carboxy-terminal jumonji domain” (JmjC) catalyzes this type of oxidative demethylation (reviewed in references 34 and 35). The JmjC domain is located in the amino-terminal portion of the Cbfa protein, between amino acids 113 and 280. This domain is followed by two cysteine-rich, zinc

finger-like regions located at positions 373 to 414 (ZF1) and 492 to 550 (ZF2). Downstream of the ZF motifs is a distinct region of 217 amino acids that consists of 50% asparagine residues; therefore, this region is referred to as the Cbfa asparagine-rich domain (NRD). The Cbfa NRD separates the JmjC/ZF region of the Cbfa protein from the CTD (Cbfa CTD), which spans 230 amino acids and contains a single AT hook.

Dictyostelids are classified into four major groups based on their phylogenetic relationships (36). *D. discoideum* belongs to the latest diverged group, 4. On the basis of the primary structure of *D. discoideum* Cbfa (14), we obtained partial sequences of the *cbfa* genes from eight other group 4 species by PCR with degenerate primers. These data were complemented with full-length *cbfa* genes obtained from the recently completed genome sequencing projects for the group 4 species *D. purpureum* (5), the group 3 species *D. lacteum* (G. Glöckner, unpublished data), the group 2 species *P. pallidum* (4) and *A. subglobosum* (available in the *Acytostelium* Genome Database), and the group 1 member *D. fasciculatum* (4). Sequences of the *cbfa* genes derived from genome sequencing projects were confirmed by sequencing genomic DNA and cDNA (data not shown). An alignment of 14 dictyostelid Cbfa proteins is presented in Fig. S3 in the supplemental material.

Within group 4, the level of identity between the JmjC/ZF domains ranges from 74 to 97% and covers ~550 amino acids. The Cbfa proteins from the organisms in groups 1 to 3 are more than 45% identical to the JmjC/ZF region of Cbfa of *D. discoideum*. Cbfa-like zinc finger regions (see Fig. S4 in the supplemental ma-

FIG 4 Expression of CbfA CTD in JH.D cells. (A) Western blot assays illustrating expression levels of the GFP-tagged *D. discoideum* CbfA CTD and the *P. pallidum* CbfA CTD in JH.D cells. Total cell extracts were prepared from AX2 and JH.D cells and the three JH.D transformants that were used for RNA-seq experiments. Shown is a single blot that was successively stained with CbfA monoclonal antibody 7F3 (which recognized *D. discoideum* CbfA CTD but not *P. pallidum* CbfA CTD), a GFP-specific antibody, and a polyclonal antiserum specific for actin (loading control). Values to the left indicate molecular mass markers (kilodaltons). (B) Cellular localization of the GFP-tagged *D. discoideum* CbfA CTD and the *P. pallidum* CbfA CTD in JH.D live cells. Top panel, DAPI staining; middle panel, GFP fluorescence; bottom panel, merged DAPI and GFP fluorescence overlaid with a phase-contrast picture. Note that a *D. discoideum* culture usually contains a fraction of multinucleated cells. Cells with two nuclei are compared here. Bars, 10 μm.

terial) are found in proteins from plants and animals; however, these proteins contain either ZF1 or ZF2 and are not linked with a JmjC domain. The CbfA-like combination of JmjC and ZF1/ZF2 domains was detected in proteins from several filamentous fungi (but not yeasts). Furthermore, this structure was detected in a protein of unknown function from the amoeboflagellate *Naegleria gruberi*. A protein with similarity to CbfA was also detected in the genome of the amoebozoan *Acanthamoeba castellanii* (Glöckner, unpublished). As discussed below, the CbfA-archetypical JmjC/ZF1/ZF2 design combined with the divergence of the CTDs defines a new family of “C-module-factor-like proteins.”

CbfA CTDs are well conserved, with sequence identities ranging from 81 to 98% in group 4 and >40% in the non-group 4 species compared with *D. discoideum* CbfA. This *D. discoideum* CbfA CTD is later referred to as the CTD “core” because CbfA CTDs from non-group 4 species are considerably extended (see Fig. S3 in the supplemental material). CbfA CTD extensions range from 140, 223, 107, and 255 amino acids in CbfA from *D. lacteum*, *P. pallidum*, *A. subglobosum*, and *D. fasciculatum*, respectively. These extensions do not display any detectable sequence homology with each other, despite the strong conservation of the CTD core.

The CTD of CbfA displays deeply conserved gene regulatory functions. Having established a comprehensive list of CbfA-regulated genes in growing *D. discoideum* cells from the RNA-seq data, we next investigated whether the CbfA CTD could repair the aberrant gene expression in JH.D cells. The cells were transformed with a plasmid containing a GFP-tagged *D. discoideum* CbfA CTD

variant under the control of a constitutive promoter. As shown in Fig. 4A, the expression of the CbfA CTD was higher than the endogenous CbfA levels in AX2 cells, and the CbfA CTD protein was enriched in the nuclei of JH.D transformants (Fig. 4B). These transformants were used for RNA-seq experiments, and gene expression levels were compared with those of AX2 and JH.D cells. Gene expression levels in JH.D cells that were 50% of the levels in AX2 cells were considered to be successfully restored by CbfA CTD transformation. Thus, 85% of the CbfA-activated and 76.7% of the CbfA genes were responsive to CbfA CTD. With a more stringent threshold of 80% of the wild-type expression level, we still determined that 76.5% of the CbfA-activated genes and 47.3% of the CbfA-repressed genes were complemented by the expression of the CbfA CTD in the CbfA mutant. We observed a pronounced overcomplementation in the mutant cell transformants; 69.5% of the CbfA-activated genes in the CbfA CTD-transformed mutant cells were expressed at levels higher than those observed in wild-type cells (see Table S2 in the supplemental material). The overcomplementation phenomenon in the mutant cells could result from the overexpression of the CbfA CTD. Alternatively, the JmjC/ZF region of CbfA may modulate the activity of the CTD in the full-length protein. In summary, the CbfA CTD may function to regulate the majority of the CbfA-regulated genes without requiring the JmjC/ZF domains.

We next determined whether the CbfA CTD of a dictyostelid species that diverged early would be functionally equivalent to the *D. discoideum* CbfA CTD. We cloned the CbfA CTD from *P. pallidum* and expressed the gene as a GFP-tagged protein in *D. dis-*

FIG 5 Gene regulatory function of *P. pallidum* Cbfa CTD. Shown are the results from an RNA-seq experiment with JH.D cells expressing either the GFP-tagged *D. discoideum* Cbfa CTD or the *P. pallidum* Cbfa CTD. The reads were mapped to 12,317 gene models, and read counts were standardized to transcript lengths and 1 million reads (RPKM values). The mean RPKM values of three independent cultures are plotted (gray symbols). The black symbols highlight genes that were reported to show statistically significant differential levels of regulation ($P \leq 0.01$) of at least 3-fold.

coideum JH.D cells (Fig. 4A). Similar to the *D. discoideum* Cbfa CTD, the *P. pallidum* Cbfa CTD was localized to the nuclei of the transformed cells (Fig. 4B). RNA-seq data revealed that the expression of 73.3% of the Cbfa-activated genes (73.3%) and 51.4% of the Cbfa-repressed genes was restored by the *P. pallidum* Cbfa CTD to at least 80% of the expression level in AX2 cells. Although the expression of the *P. pallidum* Cbfa CTD in JH.D cells was considerably less than the expression of the *D. discoideum* Cbfa CTD (Fig. 4A), we observed a similar overcomplementation effect on Cbfa-dependent gene expression (64.0% of the Cbfa-activated genes were expressed at $>100\%$ of the AX2 levels; see Table S2 in the supplemental material). Thus, overcomplementation by the Cbfa CTD may, in fact, be a consequence of the missing JmjC/ZF region of the Cbfa protein rather than an artifact of the overexpression process.

In Fig. 5, we plotted the RNA-seq data obtained from JH.D cells expressing the *D. discoideum* Cbfa CTD versus that from the mutant cells expressing the *P. pallidum* Cbfa CTD. Gene expression differences that were less than 3-fold were not considered for analysis. We determined that only 98 (0.8%) of the 12,317 genes were differentially regulated in the two data sets. Of these genes, only 31 were identified on the list of 1,030 Cbfa-regulated genes, indicating a great functional overlap between the *D. discoideum* and *P. pallidum* Cbfa CTDs. In fact, we found that approximately 87% of the Cbfa CTD-responsive genes were restored to at least 80% of the wild-type level by both the *D. discoideum* and *P. pallidum* Cbfa CTDs. This result is notable because *D. discoideum* and *P. pallidum* have different percentages of GC content in their genomes and promoter alignments of the two species are nearly impossible (4); however, the gene regulatory function of the *D. discoideum* Cbfa CTD requires direct binding to the AT-rich DNA sequences

within the target promoters, as suggested by *in vitro* and *in vivo* data (14, 18).

Cbfa-like proteins contain conserved JmjC/ZF domains and divergent carboxy termini. “Cbfa-like proteins,” which we define in this study as proteins displaying the characteristic JmjC/ZF1/ZF2 architecture of dictyostelid Cbfa, were detected both within and outside the dictyostelid clade. The average percentage of amino acid sequence identity between Cbfa and Cbfa-like proteins from dictyostelids (i.e., paralogous Cbfb proteins) and fungi is approximately 25% in the protein regions with conserved architecture. The distinctive design of the zinc finger regions of Cbfa (see Fig. S4 in the supplemental material) provides an indication of the evolution of Cbfa and Cbfa-like proteins. The ZF1 region of Cbfb proteins shares the signature $CX_2CX_7XX_2CX_2C$ (where X is any amino acid replacing cysteine in this position) with both fungal Cbfa-like proteins and one of the earliest diverged dictyostelid, *D. fasciculatum*. This motif developed into $CX_2CX_7CX_2CX_2C$ in dictyostelid Cbfa proteins and was further expanded by a CX_2H motif found exclusively in Cbfa proteins (see Fig. S4 in the supplemental material). Importantly, a Cbfa-like protein from *Naegleria gruberi* and Cbfb from the dictyostelid *A. subglobosum* (group 2 dictyostelid) share a $CX_2CX_7CX_2XX_2X$ variant of ZF1 (X replacing cysteine in this position). In contrast to the design of the ZF1 region, that of the ZF2 region is highly conserved among Cbfa, Cbfb, and fungal Cbfa-like proteins, although the distances between the two cysteine residues in the second CX_2C motif are extended by up to 36 amino acids in the Cbfb proteins.

The arrangement of the cysteines in the ZF1 region suggests that the fungal Cbfa-like proteins are more closely related to the dictyostelid Cbfb proteins than to the Cbfa proteins. A phylogenetic analysis of the JmjC/ZF regions of the Cbfa-like proteins revealed a clear separation between the dictyostelid Cbfa and Cbfb proteins and their fungal orthologs (Fig. 3). To date, the Cbfa CTD has not been found in proteins from any other organisms outside the dictyostelids. In striking contrast to the conservation of the CTDs of the Cbfa proteins, the Cbfb proteins have extended CTDs that do not exhibit any signs of similarity. The Cbfb CTDs from the group 4 organisms *D. discoideum* and *D. purpureum* do not show any similarity, even though they are 85% identical in the JmjC/ZF regions. Similarly, the CTDs of the Cbfa-like proteins from fungi do not share any traceable similarities. These observations indicate that the CTDs of the Cbfa-like proteins have rapidly evolved because of either species-specific adaptation pressures or the total removal of clade-specific constraints.

DISCUSSION

Two different gene regulatory functions combined in one protein. In this study, we performed Illumina RNA-seq to extend our knowledge concerning the function of the Cbfa protein. A previous DNA microarray experiment performed with Cbfa-deficient mutant JH.D cells (18) had limited sensitivity and included only approximately half of the *D. discoideum* genes. Comparing the two transcriptomic approaches, we observed that only 35% of the 1,030 Cbfa-dependent genes identified by RNA-seq were present on the DNA microarray. Only 42 of the 365 genes were reported as Cbfa regulated in the DNA microarray experiment, where the threshold was set at a 1.5-fold change in expression, thereby suggesting that the sensitivity of the DNA microarray was lower than that of the RNA-seq approach. This assumption is supported by the observation that the detection of Cbfa-dependent genes by DNA microarray analysis was biased toward strongly expressed

genes, as illustrated in Fig. S5 in the supplemental material. Both the DNA microarray experiments and the RNA-seq analyses reported CbfA positively regulated genes that were involved in phagocytosis. However, the results obtained with the two transcriptomic methods were not similar. GO term enrichment analysis of the DNA microarray data with AmiGO version 1.8, which is the same program used to analyze the RNA-seq data, reported that 16 genes that were assigned to the cellular function of “phagocytic vesicles” were regulated by CbfA (data not shown). However, nine of these genes produced conflicting results in the RNA-seq experiment and were not detected as CbfA-dependent genes. Even more confusing was the observation that qRT-PCR analysis measuring the expression of the CbfA-regulated genes that were associated with phagocytosis did not confirm the prediction from RNA-seq. Because we used different cultures for the RNA-seq and qRT-PCR experiments, we hypothesize that the expression of genes involved in phagocytosis is considerably variable and culture dependent.

Consistent with the previous DNA microarray data (18), we found with RNA-seq that the CbfA CTD core exerts the majority of its gene regulatory activity without requiring the other domains of CbfA. Thus, CbfA can be divided into two independently functioning regions: the JmjC/ZF region and the CTD. At present, we are not able to determine how the JmjC/ZF region of the CbfA protein contributes to CbfA function. In the experiments presented here, approximately two-thirds of the CbfA-mediated gene regulation was mediated by the CbfA CTD alone. Thus, the JmjC/ZF region of CbfA may only function as a regulatory domain to modulate the CbfA CTD. However, there is evidence that the JmjC/ZF portion of CbfA is required for gene regulatory functions that cannot be carried out by the CbfA CTD alone. For example, the CbfA CTD was not able to rescue the developmental defect in CbfA-deficient JH.D cells (18). The fact that CbfA-deficient cells have a strong developmental phenotype indicates that CbfB, which is expressed in the CbfA mutant at normal levels, is not able to complement the loss of CbfA. Nevertheless, we cannot exclude the possibility that the number of genes regulated by the JmjC/ZF region of CbfA has been underestimated in our study because of a partial overlap of CbfA with similar functions of the CbfB-derived JmjC/ZF domain. This question will be addressed once a CbfB-deficient mutant becomes available.

Preliminary data have suggested that the JmjC/ZF portion of CbfA is sufficient to rescue JH.D cell development in the absence of the CbfA CTD, which would imply that the two domains of the CbfA protein function independently (S. Gatz and T. Winckler, unpublished data). This finding would suggest that gene regulation mediated by the CbfA CTD depends on the direct binding to specific promoter regions in target genes; gene regulation mediated by the ectopically expressed CbfA CTD is compromised by mutations in the AT hook motif (18). It is tempting to speculate that the JmjC/ZF domain of CbfA acts as a chromatin modifier without directly binding to DNA. This possibility would assume that the CbfA zinc fingers have functional parallels with plant homeodomain (PHD) fingers, which are known to interpret the histone code by binding to nucleosome core histones in a modification-dependent manner (37, 38). CbfA displays significant similarity to the *Neurospora* DMM-1 protein in both the JmjC and ZF domains but not in the CTD. DMM-1 is required to inhibit the spreading of histone 3 lysine-9 methylation from transposable element loci into nearby genes (39). Notably, both the JmjC and

ZF domains are required for the function of DMM-1, while the distinct CTD of DMM-1 is dispensable, even though the presence of multiple AT hooks in the DMM-1 CTD would have suggested a role for this region in directing the protein to its target sequences. In fact, DMM-1 requires interactions with the DMM-2 protein to interact with target DNA (39).

Rapid evolution of CTDs. In this study, we defined a new family of “C-module-binding factor-like proteins” that are characterized by the unique combination of a JmjC domain and CbfA-archetypical zinc fingers. CbfA-like proteins emerged before the dictyostelid split, and the dictyostelid clade is characterized by the emergence of a second CbfA-like protein, i.e., CbfB. Whereas CbfA-like proteins are characterized by the rapid evolution of the CTDs, the CbfA CTD is highly conserved and is detectable only in the dictyostelid clade. The question that remains is whether CbfA has diverged from a CbfB-like ancestor or vice versa. The differences in the ZF1 region in the CbfA and CbfB proteins suggest that the CbfB proteins represent the ancestral variant of the ZF1 region. This region was subsequently expanded to the dictyostelid-specific CbfA proteins by the addition of the CX₂C and CX₂H motifs (see Fig. S4 in the supplemental material). Assuming that the zinc finger(s) in the CbfA proteins may be involved in the binding to specific histone modifications as a part of an intrinsic chromatin regulatory function similar to the plant PHD fingers (37, 38), it is possible that adaptations in the ZF1 region have yielded functional specifications in the JmjC/ZF regions of the CbfA and CbfB proteins. This hypothesis can be evaluated by comparing the gene expression in CbfA- and CbfB-deficient mutants. We speculate that CbfA arose in the dictyostelid clade by the duplication of an ancestral CbfA-like protein that consisted of a CbfB-like JmjC/ZF region and an unknown CTD. The recent discovery of a CbfA-like protein within an *Acanthamoeba* protein (Glöckner, unpublished) supports the suggestion that CbfA derived from the dictyostelid lineage by gene duplication from a CbfB-like ancestor. The CbfA CTD may have been a part of the ancestral CbfA-like protein that has been maintained by evolutionary pressures to serve common gene regulatory functions. Whether the rapid divergence of the CTDs in CbfA-like proteins (including *D. discoideum* CbfB) occurred through a mutation in a preexisting CTD or by frequent domain swapping remains unknown. The extended CbfA CTDs in the earlier dictyostelids may mediate functions specialized to the individual properties of the respective genomes.

The data presented in this study suggest that evolution has combined two independent gene regulatory functions into a single protein; whereas one of the regulatory elements was notably well conserved (JmjC/ZF), the other (CTD) was highly variable. This variability enabled the adaptation to the high genome flexibility that occurred in dictyostelid evolution (4). We predict that, similar to the CbfA CTDs, the CbfB CTDs have autonomous gene regulatory functions, but these functions are specialized to individual genomes and do not exhibit much overlap between species. However, a complete loss of function of this domain is also possible. This hypothesis can now be further tested experimentally on the basis of the data presented in this paper.

ACKNOWLEDGMENTS

We are grateful to H. Urushihara of the University of Tsukuba and A. Kuspa of the Baylor College of Medicine for discussing data from comparative dictyostelid genome projects prior to publication. We thank P.

Schaap for depositing many of the dictyostelid strains required for this study at the *Dictyostelium* Stock Center, and we thank the Stock Center staff for providing these strains.

ABSTRACT

Dictyostelium intermediate repeat sequence 1 (DIRS-1) is the founding member of a poorly characterized class of retrotransposable elements that contain inverse long terminal repeats and tyrosine recombinase instead of DDE-type integrase enzymes. In *Dictyostelium discoideum*, DIRS-1 forms clusters that adopt the function of centromeres, rendering tight retrotransposition control critical to maintaining chromosome integrity. We report that in deletion strains of the RNA-dependent RNA polymerase RrpC, full-length and shorter DIRS-1 messenger RNAs are strongly enriched. Shorter versions of a hitherto unknown long non-coding RNA in DIRS-1 antisense orientation are also enriched in *rrpC*[−] strains. Concurrent with the accumulation of long transcripts, the vast majority of small (21 mer) DIRS-1 RNAs vanish in *rrpC*[−] strains. RNASeq reveals an asymmetric distribution of the DIRS-1 small RNAs, both along DIRS-1 and with respect to sense and antisense orientation. We show that RrpC is required for post-transcriptional

DIRS-1 silencing and also for spreading of RNA silencing signals. Finally, DIRS-1 mis-regulation in the absence of RrpC leads to retrotransposon mobilization. In summary, our data reveal RrpC as a key player in the silencing of centromeric retrotransposon DIRS-1. RrpC acts at the post-transcriptional level and is involved in spreading of RNA silencing signals, both in the 5' and 3' directions.

INTRODUCTION

Cellular RNA-dependent RNA Polymerases (RdRPs) are present in many eukaryotic organisms, including mammals (1), are involved in mechanisms of RNA-mediated gene regulation including RNA interference (RNAi) (2,3). RdRPs synthesize an RNA strand from a complementary RNA template, leading to either long or small antisense transcripts. Based on *in vivo* and *in vitro* studies, including deep sequencing analyses, several primer-dependent and -independent modes of action have been inferred for RdRPs from different organisms. These frequently lead to an amplification of a primary silencing signal such as double-strand-derived small interfering RNA (siRNA). An amplifying component

was postulated by Fire and Mello when they first described RNAi in *Caenorhabditis elegans* (4), leading to the identification of RdRP EGO-1 as the responsible enzyme (5). When RNA was injected against a reporter gene, secondary siRNAs were observed that predominantly localize 5' of the original trigger, and this 5' spreading was shown to be RdRP-dependent (6). This phenomenon, known as 'transitivity', is diagnostic for RdRP activity *in vivo* (6–8). We recently observed transitivity in the amoeba *Dictyostelium discoideum*, and have shown that it depends on the presence of the RdRP RrpC and the dicer-related nuclease DrnB, as inferred from an artificial reporter system (9). RrpC is one of three RdRPs in *D. discoideum*, all of which show a similar domain structure (Supplementary Figure S1) (10).

Dictyostelium intermediate repeat sequence 1 (DIRS-1) is the founding member of a poorly characterized class of long terminal repeat (LTR) retrotransposons. DIRS elements differ from other LTR retrotransposons by having inverted instead of direct terminal repeats, lacking an aspartic protease domain and using a tyrosine recombinase instead of a DDE-type integrase protein for integration. Thus, DIRS elements use a retrotransposition mechanism fundamentally different from that of other LTR retrotransposons [reviewed in (11)]. This may favor the recombinatorial integration into preexisting copies of the same element as seen in the *D. discoideum* genome. The genome of *D. discoideum* features ~40 intact copies and ~200–300 fragments of DIRS-1, which thus represents the most frequently occurring LTR retrotransposon in the amoeba (12). DIRS-1 sequences accumulate at one end of each chromosome (12), and these clusters have been suggested to represent the centromeres of the chromosomes in *D. discoideum* (13,14). Although observed clustering of DIRS-1 elements may result from preferential integration of mobilized DIRS-1 copies into preexisting DIRS-1 clusters (15), it is not known whether the apparent clustering of these elements is the result of deleterious integration into coding regions of the haploid *D. discoideum* genome that removes affected cells from the population (16). Nonetheless, uncontrolled amplification of DIRS-1 elements and integration into centromeric regions may seriously compromise centromere stability, and thus genome integrity.

DIRS-1 is transcribed as a 4.5-kb-long messenger RNA (mRNA) with three overlapping open reading frames (ORFs) (Figure 1A) (17). The left LTR possesses promoter activity to drive the transcription of the DIRS-1 mRNA (18). These DIRS-1 mRNA transcripts were found to accumulate during *D. discoideum* development and contain parts of the two LTRs (18). Additionally, heat shock or other stress conditions can trigger the expression of a 900-nt-long antisense transcript (Figure 1A), which, however, is not expressed under the axenic growth conditions applied in this study (19,20).

For retrotransposition to occur, the mRNA is thought to be reverse transcribed by the enzyme activity of ORF III (17). The ends of the resulting linear complementary DNA (cDNA) feature the LTR fragments, which exhibit sequence complementarity to a DIRS-1 region termed the internal complementary region (ICR). According to a

model put forward by Lodish *et al.* the ICR serves to bring the 5'- and the 3'-end of the reverse transcript together (11) to generate a single-stranded circular DNA replication intermediate that serves as template for the generation of a double-stranded circular DNA to be inserted in the genome (17).

We have shown earlier that the LTR of DIRS-1 is methylated by the sole DNA methyltransferase, DnmA, identified in *D. discoideum* (21). Surprisingly, no transcriptional activation was observed in a *dnmA* gene deletion strain, indicating that DIRS-1 is not under transcriptional control, at least not by DnmA. However, in that study, we observed that regulation of DIRS-1 expression may be controlled at the post-transcriptional level involving small RNAs (21). Here, we show that RrpC controls DIRS-1 post-transcriptionally, and its activity is required to prevent DIRS-1 retrotransposition. We further report RrpC-dependent spreading of an RNA silencing signal in the 3' direction in *D. discoideum*.

MATERIALS AND METHODS

Oligonucleotides

DNA oligonucleotides (Sigma) used in this study are listed in Supplementary Table S1.

Genes and strains

All experiments were carried out with AX2 and derivatives. All *D. discoideum* strains were grown axenically in HL5 medium. The *rrp* genes are listed in the online resource dictybase.org with their accession numbers DDB_G0289659 (*rrpA*), DDB_G0291249 (*rrpB*) and DDB_G0280963 (*rrpC*), and the generation of their single and multiple deletion strains was described recently (9). The *trx-1* gene has the accession number DDB_G0294447.

RNA isolation

Total RNA was isolated from 5×10^7 cells of axenically grown *D. discoideum* strains using TRIzol® (Invitrogen). Cells were pelleted for 5 min at 500 rcf/4°C and washed in 20 ml pre-cooled Sorenson phosphate buffer (2 mM Na₂HPO₄, 15 mM KH₂PO₄, pH 6.0, with H₃PO₄). On re-centrifugation of cells under the same conditions, they were lysed in 1 ml of TRIzol® reagent for 5 min. On addition of 200 µl of chloroform, the material was vortexed and incubated for 3 min at room temperature. Phases were separated by centrifugation at 16 000 rcf/4°C for 20 min. RNA was precipitated by addition of equal amounts of 100% isopropanol, incubation for 10 min at room temperature and centrifugation at 16 000 rcf/4°C for 15 min. On washing twice with 70% ethanol, the pellet was dried and re-suspended in 150 µl dH₂O. RNA concentration was determined using a NanoDrop spectrophotometer (Pqlab).

Northern blotting

For total RNA blots, 10 µg was separated by gel electrophoresis in a 1.2% GTC-agarose gel in 1 × Tris

borate + ethylenediaminetetraacetic acid (pH 8.2). On capillary transfer to nylon membranes (Roti®-Nylon plus), ultraviolet cross-linking was carried out (0.5 J/cm²). Pre-hybridization and hybridization were carried out in Church buffer [500 mM sodium phosphate (pH 7.2), 1 mM ethylenediaminetetraacetic acid, 7% w/v sodium dodecyl sulphate (SDS), 1% w/v bovine serum albumin] using radioactively labeled *in vitro* transcripts or polymerase chain reaction (PCR) products. Hybridization conditions are summarized in Supplementary Tables S2 and S3. All blots were washed twice for 15 min in 2 × saline sodium citrate (SSC), 0.1% w/v SDS, twice for 10 min in 1 × SSC, 0.1% w/v SDS and twice for 5 min in 0.5 × SSC, 0.1% w/v SDS. As control, blots were hybridized on stripping to probes against actin6 mRNA.

For small RNA blotting, 20 µg total RNA was separated by gel electrophoresis in a 11% polyacrylamide gel in 20 mM MOPS (pH 7.0). On electroblotting onto a nylon membrane (Amersham Hybond™-NX) for 10 min at 20 V in dH₂O (semi-dry), RNA was chemically cross-linked as described recently (22). Small RNAs were probed with 5' radioactively labeled DNA oligonucleotides as summarized in Supplementary Table S4. All other procedures were carried out as described for ultraviolet cross-linking, except for the use of the small nucleolar RNA (snoRNA) DdR-6 as loading control.

Southern blotting

Isolation of genomic DNA from 1.2×10^8 *Dictyostelium* cells for Southern blotting (23) was performed as described (24). For DNA digestion with restriction enzymes, aliquots containing 20 µg of DNA were incubated with *Sac* I, *Kpn* I or *Eco* RI (20 U/10 µg of DNA). After precipitation, samples were separated on 1.2% agarose gels for 14 h at a field strength of 1.5 V/cm, and fragments were visualized by ethidium bromide staining (0.5 µg/ml) for 30 min. DNA was denatured by soaking the gel in 10 volumes of denaturation buffer (1.5 M NaCl, 0.5 M NaOH) for 45 min, followed by 45 min soaking in neutralization buffer (3 M NaCl, 0.5 M Tris-HCl, pH 7). DNA fragments were transferred to a nylon membrane as described (25). Cross-linking and hybridization were carried out as described for northern blotting, using the right element sequence, labeled with [α -³²P]dATP by random priming. On overnight incubation, the membrane was washed with 3 × SSC, 0.01% SDS and then with 0.1 × SSC, 0.1% SDS, each at 60°C and for 1 h.

Generation of expression constructs

pTX-DIRS-1rLTRfw-GFP was generated by initially digesting the original vector pTX-GFP (26) with *Sal* I and ligating the oligonucleotides pTX-MCS-fw and pTX-MCS-rev for generating a multiple cloning site (MCS). Depending on the orientation of the MCS, the resulting vectors were termed pTX-MCSfw-A15-GFP and pTX-MCSrev-A15-GFP. To insert the DIRS-1 rLTR-sequence, plasmid pGEM®-T Easy DIRS-1 rLTR (21) was digested with *Sac* II and *Sal* I. Ligation into the

MCS of pTX-MCSfw-A15-GFP and pTX-MCSrev-A15-GFP yielded the plasmids pTX-DIRS-1rLTRfw-A15-GFP and pTX-DIRS-1rLTRrev-A15-GFP. The former was digested with *Sac* II and *Xho* I to isolate the expression cassette, which was ligated into the vector pLPBLP (27), that had been digested with the same enzymes beforehand. From this, the Actin15-promoter was removed by a restriction digest with *Hind* III and *Xho* I. The 5' overhangs were filled by Klenow fragment before ligation, and the expression cassettes without Actin15-promoter were ligated back in the original vector using a *Sac* II and *Xho* I, which yielded the plasmid pTX-DIRS-1rLTRfw-GFP. From pTX-DIRS-1rLTRrev-A15-GFP, the expression cassette was removed with *Sal* I and *Bam*HI and ligated into the vector pJET1-H2Bv1, from which the H2Bv1 fragment had been removed with the same enzymes. The actin15-promoter was removed by a digest with *Hind* III and *Sac* II, and the vector was religated on removal of 5' overhangs using Klenow fragment. The expression cassette was back-cloned into the original vector using *Sal* I and *Bam*HI, yielding plasmid pTX-DIRS-1rLTRrev-GFP.

The DIRS-1 ORFs were amplified by PCR using primers listed in Supplementary Table S1. PCR products were ligated into the cloning pJET1.2/blunt, and the resulting plasmids were sequenced. The ORF DNAs were excised by means of *Bam*HI and *Spe* I digests and ligated into pDM323 (28) that was previously linearized with *Bgl*II and *Spe* I. The resulting plasmids were transformed in AX2 and *rrpC* knockout strains, and transformation populations were used for further experiments. For the GFP-alone control, plasmid pDM317 (28) was used that features an ATG in front of the GFP coding sequence, allowing to monitor GFP expression by western blotting.

Fluorescence *in situ* hybridization and microscopy

Fluorescence *in situ* hybridization (FISH), using digoxigenin-labeled dNTPs, and 4,6-diamidino-2-phenylindole (DAPI) staining were performed as described recently (29). For the generation of probes for FISH, oligonucleotides DIRS1 forward and DIRS1 reverse were used, resulting in a 503-nt-long single-stranded DNA of DIRS-1 sense or antisense orientation, depending on their relative concentration in asymmetric PCRs. The fragment begins at the left end (LE) of ORF III (Figure 1) and is extended by 200 nt. Pictures were generated using an Alexa Fluor 488-coupled secondary antibody.

Quantitative real-time PCR

Expression analysis by quantitative real-time PCR (qRT-PCR) was carried out as described recently (30,31). In brief, total RNA was isolated using the Qiagen RNeasy Mini kit according to the provided protocol from 2×10^7 cells that were collected from exponentially growing cells and frozen at -80°C until further use. cDNA was synthesized by reverse transcription of 500 ng of total RNA using an oligodeoxythymidine primer and the Qiagen Omniscript RT kit. The Q1 and Q2 fragments of DIRS-1 were amplified from oligo(dT)-primed cDNA

Figure 1. DIRS-1 expression. (A) Schematic representation of the DIRS-1 retrotransposon with the left and right inverted LTRs (l LTR and r LTR, respectively). The three ORFs, encoding the GAG protein (ORF I), the tyrosine recombinase (ORF II) and reverse transcriptase/RNase H domain and a methyltransferase (ORF III) are displayed together with the 900-nt E1 antisense transcript. Positions for expression analysis are Q1 and Q2 for qRT-PCR and LE and RE for northern blots. (B) Expression of DIRS-1 sequences in the indicated gene deletion strains, relative to the AX2 wild-type, as monitored by qRT-PCR using primer pairs at positions Q1 and Q2, and normalized to GAPDH expression. (C) Northern blot analysis of RNA from the indicated strains, using DIRS-1 sense strand-specific probes at positions LE (left) and RE (right). Ethidium bromide-stained rRNA served as loading control, while in northern blots, an actin6 probe acted to monitor transfer efficiency. (D) Northern blots using DIRS-1 antisense strand-specific probes at positions LE (left) and RE (right). Other details are as in (C). Size ranges of signals for shorter antisense RNAs are indicated to the right of each blot. Northern blot conditions are listed in Supplementary Tables S2 and S3. See also Figures 2 and 3 and Supplementary Figure S2.

with primer pairs Q-DIRS-01/-02 and Q-DIRS-03/-04, respectively. Expression of DIRS-1 was standardized against expression of the GAPDH gene, which was amplified using primers Q-gpdA-01 and Q-gpdA-02. Real-time amplification was carried out on a Stratagene Mx3000P instrument in 25 μ l reaction mixes containing 1 \times Taq buffer, 0.2 mM deoxynucleoside triphosphates, 0.4 μ M primers, 1 \times ROX reference dye (Jena Bioscience, Germany), 1 \times EvaGreen solution (Jena Bioscience, Germany), varying amount of cDNA and 1.25 U Taq polymerase (Jena Bioscience, Germany). After an initial denaturing step at 95°C for 10 min, the PCR was performed for 40 cycles at 95°C for 30 s, 58°C for 30 s and 72°C for 30 s. Regulation was calculated by the method of Pfaffl (32).

Deep sequencing and computational analysis

RNA was prepared and converted to cDNA, from which sequencing libraries were prepared and sequenced using the Illumina platform as described recently (33). Endogenous siRNA populations in the AX2 wild-type and *rrpC* knockout strains, each in two biological replicates, were sequenced after ligation of Illumina TruSeq small RNA adapters that allow cluster amplification on the flow cell surface. Adapter sequences were trimmed from the sequences using Cutadapt (34) with at least 3-nt overlap allowing for 10% mismatches. The trimmed reads were mapped against a reference using Bowtie2 (35). The reference was either the genome of *D. discoideum* strain AX4 (downloaded from <http://dictybase.org/>) or our own repeat sequence library containing simple repeats from Repbase (36) and consensus sequences of interspersed repeats including DIRS-1. The default setting was used when mapping to the genome reference, while a more sensitive setting was used when mapping to the repeat reference (-M 500 -N 1 -L 20 -R 3 -D 20 -i S,1,0.50). Read count per annotated region (<http://dictybase.org/download/gff3/>) was extracted with HTSeq (<http://www-huber.embl.de/users/anders/HTSeq/doc/overview.html>). The read distribution was visualized with the integrative genomics viewer (37).

RESULTS

Accumulation of DIRS-1 sense transcripts in the absence of the *rrpC* gene

In a previous study, we observed the accumulation of transcripts of the retrotransposon DIRS-1 in a gene disruption strain of the RdRP RrpC (21). To study the impact of RdRPs on DIRS-1 expression in *D. discoideum* in detail, we made use of a recently introduced series of strains (9), with the genes of the RdRPs in all possible combinations deleted by a one-step cloning strategy (38) that is based on the Cre-lox system (27). Unlike in the originally used gene disruption strains (21), both functional domains of each *rrp* gene (Supplementary Figure S1) were removed completely (9), resulting in three single, three double and one triple *rrp* gene deletion strain. In addition, DIRS-1 expression was monitored in a gene deletion strain of the dicer-related nuclease DrnB

(*drnB*[−]) (39). Analyses by qRT-PCR using the two primer sets Q1 and Q2 (Figure 1A) showed a 50–100-fold increase of DIRS-1 RNA in all *rrpC* gene deletion strains compared with the isogenic wild-type strain (Figure 1B). In the *drnB*[−] strain, a 5–10-fold increase in RNA levels was observed, depending on which primer set was used. To assess how these RNA molecules correspond to full-length DIRS-1 RNA, we next carried out northern blot analyses with riboprobes against the left-end (LE) and right-end (RE) positions in the DIRS-1 sense transcript that localize to the 5'-end or the 3' part of ORF III, respectively (Figure 1A). As shown in Figure 1C, these analyses revealed a considerable increase of a 4.5-kb fragment corresponding to the size of the DIRS-1 full-length mRNA (18) for each *rrpC* gene deletion strain, while the transcript levels in the *drnB*[−] strain appear similar to that observed in the wild-type strain (Figure 1C). In the *rrpC*[−] strains, the DIRS-1 transcripts display strong size heterogeneity as indicated by the smear in the respective lanes of the northern blots (summarized in Table 1).

A long DIRS-1 antisense transcript

Considering that antisense transcripts are prevalent, particularly in mobile genetic elements (40,41), we also used riboprobes that bind to the same LE and RE positions (Figure 1A) on an antisense transcript. We observed an RNA transcript of 4 kb by either riboprobe (Figure 1D). The existence of this hitherto unknown antisense RNA was also confirmed independently by strand-specific qRT-PCR (Supplementary Figure S2). We termed this long non-coding RNA (lncRNA) *long antisense DIRS-1* (lasDIRS-1) to discriminate it from the 900-nt E1 antisense transcript that is produced on heat shock (19,20), but not under the axenic growth conditions used in this study. Unlike the situation seen for the DIRS-1 mRNA, the lasDIRS-1 lncRNA displays a discrete size, and its RNA levels appear to be identical in either gene deletion strain investigated here. Only in the *rrpC*[−] strains was a light smear below the full-length lasDIRS-1 RNA observed reproducibly, indicating size heterogeneity (Figure 1D and summarized in Table 1).

Promoter activity of the DIRS-1 right LTR

Because the sense transcript is derived from the promoter activity of the left LTR (18), it seemed plausible that the inversely oriented right LTR sequence might contain the promoter to drive lasDIRS-1 transcription. To test this hypothesis, we generated two constructs, which contained the right LTR in forward or reverse orientation in front of a GFP expression cassette, but lacked any further promoter sequence (Figure 2A). Fluorescence microscopy of strains transformed with these two constructs revealed GFP expression only for the construct with the forward-oriented right LTR (Figure 2B). The promoter activity of the right LTR of DIRS-1 was also independently confirmed by western blotting (Figure 2C). These data strongly suggest that the lasDIRS-1 transcript derives from the right LTR of the retrotransposon.

DIRS-1 transcripts cluster in the nucleus of *rrpC*[−] cells

To determine the localization of DIRS-1 transcripts in amoeba cells, we used a recently established protocol for RNA-FISH in *D. discoideum* (29). First, we generated digoxigenin-labeled strand-specific 500-nt-long probes starting at the LE position of DIRS-1 (Figure 1A),

which we used in hybridization experiments of fixed and permeabilized AX2 wild-type and *rrpC*[−] cells. Fluorescence microscopy revealed for either probe diffuse signals that predominantly localized to the cytoplasm in AX2 wild-type cells, as judged from the DAPI staining of the nucleus (Figure 3A). In the *rrpC*[−] strain,

Figure 3. Localization of DIRS-1 transcripts in *D. discoideum* cells by FISH. Sense and antisense DIRS-1 transcripts in AX2 (A) and *rrpC*⁻ cells (B). Shown are microscopic images of fixed and permeabilized cells. First column: phase contrast; second column: DAPI staining; third column: Alexa Fluor 488-coupled secondary antibody staining of DIRS-1 transcripts; and fourth column: merge of DAPI and Alexa Fluor 488-coupled secondary antibody staining. Arrows mark accumulated transcripts. All pictures were taken at a 100-fold magnification, and a scale bar is indicated for each row in the phase contrast panel. Pictures were taken with exposure times of 260–350 ms for DAPI and 700–1000 ms for Alexa.

additional strong signals were observed (Figure 3B), which appeared to cluster in one or more spots in the nucleus. These clusters of DIRS-1 transcripts were observed by using either the sense or the antisense probe in the *rrpC*[−] strain (Figure 3B).

As summarized in Table 1, our data indicate that full-length as well as shorter sense DIRS-1 RNAs accumulates in *rrpC*[−] strains. A long antisense RNA, lasDIRS-1, is also expressed and likely driven by the promoter activity of the right LTR. Shorter fragments of lasDIRS-1 were found to accumulate in the *rrpC*[−] strains. Compared with the AX2 wild-type strain, additional signals for DIRS-1 sense and antisense transcripts appeared to localize in nuclear spots in the *rrpC*[−] strain.

DIRS-1-specific small RNAs

Because gene silencing by RdRPs is commonly associated with the appearance of small RNAs, we next analyzed the presence of DIRS-1-specific small RNAs by northern blotting. Using a radioactively labeled oligonucleotide corresponding to the LE position of the retrotransposon, we observed a significant reduction of DIRS-1-specific small RNAs in all strains lacking the *rrpC* gene as compared with the wild-type (Figure 4A). The reduction is also apparent, albeit to a lesser extent, in a northern blot using a probe against the RE position of DIRS-1 (Figure 4B). The individual deletions of the other *rrp* genes, *rrpA* or *rrpB* appeared to have no significant effect on the accumulation of these DIRS-1 small RNAs, and the same is observed for DrrB (Figure 4).

Figure 4. DIRS-1-specific small RNAs expression. Northern blots monitoring the small RNAs of DIRS-1 in the indicated strains, using oligoprobes LE (A) or RE (B), which are localized to DIRS-1 as indicated in Figure 1A. Quantification of small RNA levels (indicated below the blots) is relative to that of the AX2 wild-type and normalized to the DdR-6 snoRNA sequence (42). The 26-bp band of the size marker pUC19 DNA/*Msp*I is indicated. Northern blot conditions are listed in Supplementary Table S4.

However, with both probes, the decrease appeared less pronounced in the triple knockout strain (see also Table 1), an observation that we cannot explain at present. Yet, these northern blot data indicate that the RdRP RrpC is required for the generation of DIRS-1 small RNAs, at least at the positions LE and RE (Figure 1A). In our previous study, we had observed small RNAs distributed over the entire sequence of the retrotransposon (21). To analyze whether all these DIRS-1 small RNAs depend on RrpC, we next carried out deep sequencing studies on RNA from *D. discoideum* AX2 wild-type and *rrpC*[−] cells.

Asymmetric distribution of small RNAs over the DIRS-1 sequence

The small RNA profiles of AX2 wild-type and *rrpC*[−] strains were determined by deep sequencing on an Illumina platform using two biological replicates per strain. This resulted in ~28 and ~16 million sequence reads of 21 nt for AX2 and *rrpC*[−], respectively. These reads were mapped against the *D. discoideum* genome and a library of repeat sequences (manuscript in preparation).

In the wild-type AX2 strain, a substantial fraction of small RNA sequencing reads (19.5%) corresponded to DIRS-1 sequences, confirming our earlier studies that used 5'-ligation-dependent cloning and SOLiD sequencing of small RNAs from the AX4 strain (43). However, in the *rrpC*[−] strain, the number of DIRS-1 sequencing reads is strongly (−65%) reduced from 5.5 to 1.9 M, indicating that RrpC might be involved in their generation. We next mapped these small RNA reads on the DIRS-1 sequence (Figure 5A). The comparison of the small RNA distribution patterns in the two biological replicates of the wild-type AX2 strain (Figure 5B) indicates that the data are highly reproducible, and the same holds for the two biological replicates of the *rrpC*[−] strain (Figure 5C).

The distribution of small RNAs over the DIRS-1 sequence appears uneven in the AX2 strain. The majority of reads coincide with ORF II, while the 5'-end of GAG appears to be devoid of any small RNAs (Figure 5B). This analysis also showed the reduction of the small DIRS-1 RNAs in the *rrpC*[−] strain, but additionally indicated that not all positions within the retrotransposon are equally affected (Figure 5C). For example, although reduced reads are observed for the majority of DIRS-1 positions in the *rrpC*[−] strain, this is not the case for the relatively small number of reads that map to the LTRs of the retrotransposon (box I, Figure 5B and C). These LTR-specific small RNAs appear to be unchanged in number and position and thus likely are independent of RrpC. A small number of reads corresponding to the 5'-end of GAG was surprisingly observed only in the *rrpC*[−] strain, but not in the AX2 wild-type (box II, Figure 5B and C). These small RNAs thus seem to disappear when RrpC is present. Reads mapping around the 3'-end of ORF I and the 5'-end of ORF II appear to be particularly reduced in the *rrpC*[−] strain (box III, Figure 4B and C), while the distribution of the majority of small RNAs in the *rrpC*[−] strain has an overall similar

Figure 5. Distribution of DIRS-1-specific small RNAs. (A) Schematic representation of the DIRS-1 sequence (for details see Figure 1A). Small RNA reads from the wild-type AX2 strain (B) and the *rrpC*⁻ strain (C) are shown for their biological duplicates (1 or 2, respectively). The DIRS-1 small RNAs of sample (1) are shown separately for sense (D) and antisense (E) orientations. All reads are mapped onto the DIRS-1 sequence in (A). The signal height corresponds to the number of small RNAs, and reads are displayed in the same scale, ranging from 0 to 400,000 reads. Regions with particularly apparent deviations between the AX2 and *rrpC*⁻ strains are boxed (I, II, III, IV).

pattern to that observed in the AX2 wild-type strain, albeit at drastically reduced numbers (box IV, Figure 5B and C). These observations suggest that both of these classes of DIRS-1 small RNAs depend on RrpC.

Asymmetric distribution of DIRS-1 small RNAs in sense and antisense orientation

In view of the presence of the *lasDIRS-1* transcript (Figures 1D and 3), we next analyzed whether the DIRS-1-specific small RNAs mapped equally in sense and antisense orientation to the retrotransposon. The results showed uneven distribution of the small RNAs, with the sense small RNAs mapping predominantly to ORF II and the antisense RNAs appearing to peak in

the region box III (Figure 5D and E). The asymmetry of sense and antisense read distribution indicates that the majority of small DIRS-1 RNAs might not be generated as classical double-stranded siRNAs.

Post-transcriptional silencing of DIRS-1 mRNAs

Because the small DIRS-1 RNAs appear to be unevenly distributed along the three ORFs of the retrotransposon, we wondered what effect they might have on these three ORFs. To investigate this question, we generated over-expression constructs, in which GFP was C-terminally fused to the full mRNA of either ORF (Supplementary Figure S3). The resulting extrachromosomal vector constructs were transformed in the AX2 wild-type and the

rrpC[−] strain. Expression of the fusion proteins was monitored by western blotting using a GFP antibody. The ORF I-GFP fusion protein was readily expressed in both strains, while expression of the other two ORFs

was not detectable in the AX2 wild-type, but notably observed in the *rrpC*[−] strain (Figure 6A and B). This indicates that the RrpC-dependent small RNAs that are present in the AX2 wild-type strain are necessary and

Figure 6. Overexpression of DIRS-1 ORFs. C-terminal GFP fusions of DIRS-1 ORF I (A) and ORF II or ORF III (B) were expressed in the AX2 wild-type and in the *rrpC*[−] strain. The expression of the fusion proteins was monitored by western blotting using a GFP antibody (see also Supplementary Figure S3). (C) Small GFP RNAs from the indicated strains were analyzed by northern blot using a strand-specific radioactively labeled probe. The sizes of a radioactively labeled RNA size marker are shown to the left. Ethidium bromide-stained rRNA served as loading control, and northern blots using a sno6 riboprobe acted to monitor transfer efficiency. (D) Expression of GFP in AX2 wild-type cells. (E) Small GFP RNAs from the indicated strains. In (A, B and D), severin or discoidin were used as loading controls, and the sizes of a protein marker are shown. M in (C and E) denotes small RNA size markers. Northern blot conditions are listed in Supplementary Table S4. Note that boxed lanes are spliced together from the same blot deleting irrelevant samples.

sufficient to silence post-transcriptionally ORF II and ORF III, but not ORF I, of the retrotransposon, even though siRNAs in the 3' half of ORF I are mostly antisense to the coding transcript and could readily abolish it.

Spreading of the RNA silencing signal in the 3' direction on the target mRNA

We have recently shown that RrpC is required for the appearance of small RNAs 5' of the original silencing signal with respect to the target RNA (9). This phenomenon is generally referred to as transitive silencing (6–8), and it is thought that the target RNA serves as the template, from which an RdRP synthesizes a complementary RNA strand. Because of the directionality of all nucleic acid polymerases, such a secondary silencing signal is expected to localize 5' of the original trigger. However, Pak and Fire reported that a subset of secondary RNAs could also localize 3' of the original trigger in *C. elegans* (44), an observation that otherwise is mainly seen in the plant kingdom (7,8,45,46). To test whether 3' spreading might also be observed in the case of the DIRS-1 ORF-GFP fusion constructs, we isolated small RNAs from these strains and used northern blot analysis to identify small RNAs derived from GFP (Figure 6C). Substantial amounts of small GFP-specific sense RNAs were detected in the ORF II-GFP and ORF III-GFP expressing cells in the AX2 wild-type background, but not in the *rrpC*[−] strain. To show that GFP itself does not cause the generation of siRNAs, we transformed the AX2 wild-type with a GFP expression construct alone, which resulted in GFP expressing cells (Figure 6D) and did not cause generation of small GFP RNAs as monitored by northern blotting (Figure 6E). The inclusion of RNA from the C-terminal GFP fusions of the DIRS-1 ORFs serves here as control for the functionality of the blot, as it otherwise would appear empty. Because the GFP was fused C-terminally to the DIRS-1 ORFs, this result indicates that spreading of an RNA silencing signal in the 3' direction exists in *D. discoideum* and depends on the presence of RrpC (summarized in Table 1). We note that a weak signal for small GFP RNAs is also present in strains where the fusion protein is not silenced, but not in the untransformed AX2 wild-type strain (Figure 6).

Mobilization of DIRS-1 in the genome of the *rrpC*[−] strain

Having shown with the ORF GFP fusions that DIRS-1 mRNAs are translated in the *rrpC*[−] strain, we next set out to analyze what effects this has on the genome of the *rrpC*[−] strain. However, the genome-wide analysis of DIRS-1 elements is hampered by the large number of DIRS-1 elements and fragments (12) and the fact that DIRS-1 retrotransposition takes place preferentially in other DIRS-1 elements or fragments (15).

To investigate whether new DIRS-1 integrations can be observed in the genome of the *rrpC*[−] strain, we subjected *rrpC*[−] and AX2 wild-type strains to extensive growth for 48 days in shaking cultures kept in the exponential growth phase by regular dilution. Under such conditions, we had earlier observed increased genomic copy numbers of

Skipper, when that retrotransposon was dysregulated in a gene deletion strain of the putative DNA methyltransferase DnmA (21). From the AX2 and *rrpC*[−] long-term cultures, genomic DNA was isolated and digested with three different restriction enzymes of which *Eco* RI and *Kpn* I cleave inside the DIRS-1 DNA (Figure 7A), whereas *Sac* I cleaves outside. The restriction patterns of genomic DNA from these two strains appeared to be highly similar (Figure 7B). In the subsequently performed Southern blot (Figure 7C), the overall picture is also similar, as might be expected given the many genomic occurrences of DIRS-1 elements. For the *Eco* RI and the *Sac* I digests, the most prominent signals from the AX2 strain appear to be more intense in the *rrpC*[−] strain genomic DNA, which may indicate an increase in DIRS-1 copy number. More importantly, we observe an additional signal at ~5 kb in the *rrpC*[−] strain in the *Kpn* I digest, clearly indicating a DIRS-1 retrotransposition event (Figure 7C). To quantify these differences in DIRS-1 copy number, Southern blotting was repeated and signals for DIRS-1 and the thioredoxin gene as loading control were quantified for two digests of genomic DNA from AX2 wild-type and the *rrpC*[−] strain (Supplementary Table S5). This analysis confirmed an increase in DIRS-1 copy numbers by >50% in the *rrpC*[−] strain compared with the AX2 wild-type, as shown by loading-corrected signal increases of 52% and 62% for the two restriction enzymes used (Supplementary Table S5). Together, the data indicate that additional genomic copies of the retrotransposon accumulate in the genome of the *rrpC*[−] strain. This is further supported by a previous analysis of DIRS-1 copy numbers in the originally generated gene disruption strain of the *rrpC* gene (21), where different DIRS-1 patterns were observed in clonal long-term cultures (M. Kuhlmann and W. Nellen, unpublished).

DISCUSSION

In the present study, we show that the RdRP RrpC acts in the regulation of the centromeric retrotransposon DIRS-1. We report that sense transcripts accumulate in strains lacking the *rrpC* gene (Figure 1; summarized in Figure 8) and concurrent with this accumulation, DIRS-1-specific small RNAs are dramatically reduced (Figures 4 and 5; summarized in Table 1). As a consequence of their absence, it is likely that the DIRS-1 ORFs II and III are no longer silenced, leading to the accumulation of DIRS-1 proteins as monitored by GFP fusions (Figure 6) and DIRS-1 retrotransposition (Figure 7) in the *rrpC*[−] cells. From these data, we propose that DIRS-1 is constitutively transcribed in wild-type cells, and these transcripts are targeted by RrpC, which thus exerts its control predominantly on the post-transcriptional level.

For the full-length DIRS-1 elements, transcription is driven by the inherent promoter activity of the two LTRs, as reported earlier for the left LTR (18) and in this study for the right LTR (Figure 2), resulting in the newly discovered lncRNA antisense transcript lasDIRS-1 (Figure 1). The observation that the full-length lasDIRS-1

Figure 7. Southern blot analysis for genomic mobilization of DIRS-1 in the *rrpC*⁻ strain. (A) Schematic representation of DIRS-1 with recognition sites of *Eco* RI and *Kpn* I that cleave within the retrotransposon sequence, while *Sac* I (not shown) does not. (B) Agarose gel electrophoresis of 20 µg genomic DNA from AX2 wild-type and *rrpC*⁻ strains, digested with the indicated restriction endonucleases. As controls for hybridization, 1 or 10 ng undigested plasmid DNA featuring the DIRS-1 sequence was applied. The sizes of the 1-kb marker fragments (ThermoScientific) are indicated. (C) Southern blot using a ³²P-labeled DNA probe corresponding to the RE position. Note that the positions with an additional or stronger signals observed for the *rrpC*⁻ genomic DNA are indicated by arrows using the same colors for *Eco* RI and *Kpn* I as in (A). Changes in patterns of DNA digested with *Sac* I, which cleaves outside DIRS-1, are denoted by black arrows.

transcript is also present in the triple *rrp* gene deletion strain excludes the possibility that it might be an RdRP product. The sense and antisense transcripts that result from the LTR promoter activities appear to have different fates in the investigated cell lines. The levels of the lncRNA lasDIRS-1 are stable, whereas those of the sense RNA vary significantly (Figure 1; summarized in Figure 8). In particular, we observe a dramatic accumulation of full-length and shorter DIRS-1 sense transcripts, next to shorter versions of the lasDIRS-1 lncRNA in all deletion strains of the *rrpC* gene (Figure 1). As shown by RNA FISH, additional DIRS-1 signals can be observed in the nucleus of *rrpC*⁻ cells (Figure 3), and it appears plausible that the accumulating shorter sense and antisense transcripts that we observe by northern blotting are contained in these spots. Bidirectional transcription has also been observed for retrotransposons in other organisms, including LINE-1 in humans (47); LINE elements, SINE elements and LTR retrotransposons in mice (48,49); Tc1 in *C. elegans* (50); and transposons in *Drosophila* (51,52).

Concurrent with the accumulation of long transcripts, we observe by northern blot analyses and by deep sequencing (Figures 4 and 5), a drastic reduction of small DIRS-1 RNAs in strains lacking the *rrpC* gene. In the deep sequencing analysis, we find the majority of small RNAs to be asymmetrically distributed between the sense and antisense orientations of the retroelement in AX2 cells. This result indicates that these small RNAs are not reaction products of one of the two Dicer-like proteins in *D. discoideum* (21,39,43), because Dicers are expected to give rise to double-stranded siRNAs (53–55), which should cover DIRS-1 symmetrically in sense and antisense orientation.

Because the majority of small DIRS-1 RNAs disappear in the absence of RrpC, the simplest explanation is that these are directly synthesized by this RdRP. The synthesis of small RNAs by RdRPs has also been described in other species, including *C. elegans* (44,56), *Neurospora crassa* (57) and *Arabidopsis thaliana* (58). Our conclusion is also in line with our recently reported discovery that RrpC is required for the 5' spreading of an RNA silencing

Figure 8. Summary of DIRS-1 RNAs in AX2 and *rrpC*[−] strains. (A) Schematic representation of the DIRS-1 sequence (for details see Figure 1A). Relative levels of DIRS-1 sense transcripts (B), antisense transcripts (C) and small RNAs (D) are shown for the AX2 wild-type (purple) and for the *rrpC*[−] (light blue) strains. Arrows in (B) and (C) represent the transcripts mapped onto the DIRS-1 element in (A). The thickness of the arrows indicates relative changes in RNA quantity. Note that RNA levels are comparable only within panels and that the positions of the shorter fragments (dotted) are not exactly determined. In (D), the distribution of small RNAs is also mapped onto the element in (A) and the height of the peaks indicates abundance, using the same relative scaling (for details see Figure 5).

signal (9). Changes in the distribution of small DIRS-1 RNAs in the *rrpC*[−] strain compared with AX2 appear to cluster in four regions (boxes I–IV in Figure 5; summarized in Figure 8), which correspond to the LTR with unchanged levels (I), to the 5′-end of GAG with small RNAs absent in AX2 (II), to a region with barely any small RNAs left (III) and to a region with reduced numbers but a similar distribution pattern (IV). For the latter, RrpC might serve as the amplifying component of a primary silencing signal, like a double-stranded RNA. Such an entity has been proposed earlier by Fire and Mello, when they discovered RNAi in *C. elegans* (4). The responsible enzyme was characterized subsequently as the RdRP EGO-1 (5). The small RNAs in region III appear to strongly accumulate in antisense orientation (Figure 5E). We propose that RrpC synthesizes these small RNAs, using the DIRS-1 sense transcript as a template. Why these RNA appear to be non-functional

in the post-transcriptional silencing of the ORF I-GFP fusion protein (Figure 6A) is currently unclear, but one possible reason is that their concentration in that region might be too low (Figure 5).

The small RNAs of the LTR region, on the other hand, appear to be unaffected by the deletion of *rrpC*, and in view of their symmetric sense and antisense distribution, they might represent Dicer products. In this respect, it is worth noting that the sense transcript has been shown to contain little of the left LTR, but nearly the entire right LTR (18). Of these expressed right and left LTR sequences, 58 nt and 33 nt, respectively, are complementary to a DIRS-1 region termed the ICR. During DIRS-1 retrotransposition, the ICR is proposed to bring the 5′-end and the 3′-end of a reverse transcript together (11), to allow for the formation of a single-stranded circular DNA replication intermediate (17). It seems plausible to suggest that such base pairing also takes

place on the RNA level, and the resulting RNA double strands would be long enough to allow for Dicer activity, giving rise to the RrpC-independent DIRS-1 LTR siRNAs (box I in Figures 5 and 8).

Although the small DIRS-1 RNAs that are present only in the absence of RrpC (box II, Figures 5 and 8) are low in number, they appear reproducibly. Similarly, elevated small RNA levels in strains lacking the functional *rrpC* gene have also been shown for endogenous microRNAs (39,43), the retrotransposon Skipper (43), and recently also in transgene silencing (9). Given that RdRPs are enzymes that synthesize RNA, small RNA accumulation in their absence is counter-intuitive. However, some RdRPs in other organisms (57,58) have been proposed to act in a small RNA primer-dependent mode, in which the RNA primer is extended, resulting in the formation of long double-stranded RNAs, which act as *bona fide* Dicer substrates. If primer extension does not take place, the primers might accumulate. In view of small RNAs from various genetic backgrounds accumulating in *rrpC*[−] strains, a primer-dependent activity of this RdRP on these sequences appears to be a plausible interpretation. Albeit indirectly, this interpretation is also supported by the observation that classical (3′ 5′) transitive silencing in *D. discoideum* depends on both, the dicer-related nuclease DnB and RrpC (9). Also for several other RdRPs, both primer-dependent and -independent modes of action have been inferred, like QDE-1 in *N. crassa* (57) or the *A. thaliana* enzyme RDR6 (58,59), which act in the primer-dependent mode also in the biosynthesis of tasiRNAs (58,60).

To our surprise, we observed significant levels of small RNAs 3′ to the endogenous DIRS-1 small RNA trigger during the analysis of the C-terminal GFP fusion constructs of the DIRS-1 ORFs (Figure 6). Substantial amounts of GFP-specific small RNAs were only detectable for the ORF II and ORF III fusion constructs, but not for ORF I-GFP. Early work on the activity of RdRPs has shown that unprimed activity is preferentially observed at the 3′-end of mRNAs (61,62). Because the small GFP RNAs are not observed in the GAG GFP construct, it appears unlikely that the GFP mRNA sequence itself is recognized as aberrant and is causative for the observed spreading in the 3′ direction. Because the presence of GFP alone does not lead to the generation of small GFP RNAs (Figures 2 and 6D and E), this possibility can be excluded. From the use of probes monitoring small GFP RNAs in the sense orientation, we conclude that these are not direct products of RrpC on the mRNA of the respective ORF GFP. Rather, they are likely processing products of an RrpC-dependant double-strand that might be targeted by one of the *D. discoideum* Argonaute or Dicer proteins.

In a previous study, we had investigated transcriptional silencing of DIRS-1 by DNA methylation. Although the DIRS-1 right LTR was found to be methylated by the sole DNA methyltransferase in *D. discoideum*, DnmA (21), a deletion of its gene did not result in a transcriptional upregulation of DIRS-1. From this, we concluded that DIRS-1 is not under transcriptional control by DnmA, unlike the retrotransposon Skipper (21). However, we

cannot exclude the possibility that other components of the heterochromatization machineries in the amoeba might add a transcriptional control of DIRS-1 in addition to the post-transcriptional control by RrpC that we report here.

Control at the post-transcriptional level appears uneconomic, as DIRS-1 transcripts are first generated in order to then be degraded. However, this control might be a consequence of the integration behavior of DIRS-1. Because DIRS-1 retrotransposition takes place preferentially into other DIRS-1 elements or fragments thereof (15), highly diverse DIRS-1 sequences are expected to be produced. In these diverse DIRS-1 sequences, motifs other than the LTRs might serve as promoters, which then might render the mobile genetic elements refractory to transcriptional control, at least by using LTR promoter methylation.

Abstract

Background: In the compact and haploid genome of *Dictyostelium discoideum* control of transposon activity is of particular importance to maintain viability. The non-long terminal repeat retrotransposon TRE5-A amplifies continuously in *D. discoideum* cells even though it produces considerable amounts of minus-strand (antisense) RNA in the presence of an active RNA interference machinery. Removal of the host-encoded C-module-binding factor (CbfA) from *D. discoideum* cells resulted in a more than 90 % reduction of both plus- and minus-strand RNA of TRE5-A and a strong decrease of the retrotransposition activity of the cellular TRE5-A population. Transcriptome analysis revealed an approximately 230-fold overexpression of the gene coding for the Argonaute-like protein AgnC in a CbfA-depleted mutant.

Results: The *D. discoideum* genome contains orthologs of RNA-dependent RNA polymerases, Dicer-like proteins, and Argonaute proteins that are supposed to represent RNA interference pathways. We analyzed available mutants in these genes for altered expression of TRE5-A. We found that the retrotransposon was overexpressed in mutants lacking the Argonaute proteins AgnC and AgnE. Because the *agnC* gene is barely expressed in wild-type cells, probably due to repression by CbfA, we employed a new method of promoter-swapping to overexpress *agnC* in a CbfA-independent manner. In these strains we established an in vivo retrotransposition assay that determines the retrotransposition frequency of the cellular TRE5-A population. We observed that both the TRE5-A steady-state RNA level and retrotransposition rate dropped to less than 10 % of wild-type in the *agnC* overexpressor strains.

Conclusions: The data suggest that TRE5-A amplification is controlled by a distinct pathway of the *Dictyostelium* RNA interference machinery that does not require RNA-dependent RNA polymerases but involves AgnC. This control is at least partially overcome by the activity of CbfA, a factor derived from the retrotransposon's host. This unusual regulation of mobile element activity most likely had a profound effect on genome evolution in *D. discoideum*.

Background

Transposable elements are found in virtually all organisms and play central roles in shaping their host's genomes. The amplification of these genomic parasites is a constant threat to host fitness due to the intrinsic process of integration into the genomic DNA that can cause mutagenesis of genes and force illegitimate recombinations between distant transposon copies [1–4]. Eukaryotic cells have evolved several pathways of RNA interference (RNAi) to restrain the amplification of transposons at the posttranscriptional level [5–8]. In this process, long RNA duplexes (dsRNA), which may occur in cells as intermediates of transposon or RNA virus replication, are typically processed into 20–30 nucleotide double-stranded small interfering RNAs (siRNAs) by ribonuclease III-type enzymes such as Dicer. The siRNAs are loaded onto RNA-induced silencing complexes (RISCs), which are minimally composed of an Argonaute protein and a small RNA [9, 10]. Argonaute proteins are characterized by an RNA-binding PAZ (Piwi-Argonaut-Zwille) domain and a catalytic, ribonuclease H-like PIWI (P-element-induced wimpy testis) domain. Argonaute proteins bind siRNAs via their PAZ domains, unwind the siRNA duplex and use one of the single-stranded RNA molecules as guides to bind mRNAs in a sequence-specific manner [9]. If the guide RNA is fully complementary to the target RNA across the active site of the Argonaute protein, the enzyme is able to degrade the target RNA by a single endonucleolytic cut executed by the PIWI domain, a function termed slicing. If slicing is precluded by mismatches between the annealing guide RNA and cellular mRNA, translation is repressed and mRNA can be degraded by deadenylation and decapping.

The social amoeba *Dictyostelium discoideum* has a haploid genome in which nearly two thirds of DNA are protein-coding genes [11]. Despite the remarkable compactness of its genome, *D. discoideum* accommodates a large number of mobile elements that add up to approximately 10 % of the entire genomic DNA [12]. Most likely for the purpose of suppressing transposition, the organism has evolved a sophisticated RNAi machinery that includes, for example, three RNA-dependent RNA polymerases (RdRPs), two Dicer-like proteins, and five Argonaute-like proteins [13–17]. Intriguingly, the non-long terminal repeat retrotransposon TRE5-A has established a fairly high amplification rate in growing *D. discoideum* cells [18, 19] despite the constitutive production of minus-strand RNA from an element-internal promoter [20, 21]. Thus, how TRE5-A manipulates the cellular RNAi machinery to maintain its remarkable retrotransposition activity is of interest.

Clearly, *D. discoideum* cells could take advantage of TRE5-A's minus-strand RNA production to downregulate TRE5-A plus-strand RNA, the substrate for

retrotransposition, using an RNAi pathway. This strategy is actually realized in the silencing of the tyrosine recombinase retrotransposon DIRS-1 in *D. discoideum* cells [22]. To suppress TRE5-A amplification, promoter activity of the C-module, the distinguished minus-strand RNA promoter at the 3' end of the TRE5-A element, could be positively regulated by a host-encoded transcription factor. This could elevate the level of TRE5-A-derived dsRNA, which could be processed into small RNAs that guide Argonaute proteins to degrade TRE5-A plus-strand RNA and prevent retrotransposition. Consistent with this idea, we previously isolated the C-module-binding factor (CbfA), a host-encoded DNA-binding protein that interacts with the C-module of TRE5-A in vitro [23–25].

The gene *CbfA*-coding could not be inactivated by conventional homologous recombination (knockout) and may be essential for the growth of *D. discoideum* cells. We constructed a knock-in mutant, JH.D, in which the *cbfA* gene was replaced by a *cbfA* variant containing an amber stop codon at amino acid position 455 [25]. The expression of an amber suppressor tRNA gene in *D. discoideum* cells allows read-through translation without causing an inherent phenotype [26]. Due to the low efficacy of this amber suppression, JH.D cells produce less than 5 % of full-length CbfA protein from the expressed *cbfA*(amber) mRNA [25].

JH.D cells have an aberrant developmental phenotype that can be fully rescued by ectopic expression of CbfA in the mutant [27]. Transcriptome analyses revealed that CbfA has general gene regulatory functions in *D. discoideum* cells [28], making this protein an attractive candidate as a host protein that could limit TRE5-A expression and retrotransposition by elevating TRE5-A-derived minus-strand RNA. Interestingly, we observed that both plus- and minus-strand RNA of TRE5-A were reduced concurrently in the CbfA mutant by more than 90 %, and this reduction of transcript levels was accompanied by a sharp drop in TRE5-A's retrotransposition activity in vivo [21]. Remarkably, the promoter activity of neither the A-module (TRE5-A's plus-strand RNA promoter) nor the C-module was altered in reporter gene assays in the CbfA mutant compared to wild-type cells [21]. Thus, we hypothesized that CbfA supports TRE5-A amplification indirectly by down-regulating one or several components of the cellular RNAi machinery. In support of this assumption, a previous transcriptome analysis revealed an approximately 230-fold and 3-fold overexpression of the genes encoding *D. discoideum* Argonaute-like proteins AgnC and AgnE, respectively, in the CbfA-depleted mutant [28].

Here, we found that TRE5-A expression was elevated in knockout strains of *agnC* and *agnE*, suggesting that CbfA may support the accumulation of TRE5-A transcripts by suppressing an RNAi pathway that involves these Argonaute proteins. To determine whether control

of TRE5-A expression by AgnC and/or AgnE leads to a reduction in TRE5-A retrotransposition *in vivo*, we first developed a new gene activation (GA) strategy to construct strains that overexpress *agnC* in the absence of any residual plasmid sequences inserted in their genomes. We found that the accumulation of TRE5-A RNA was reduced in both *agnC^{GA}* and *agnE^{GA}* strains. Next, we employed the previously developed “TRE trap” retrotransposition assay [18, 19] to determine the retrotransposition activity of the cellular TRE5-A population in *agnC^{GA}* cells. The retrotransposition frequency of the cellular TRE5-A population was determined to be less than 10 % of the wild-type level, suggesting that TRE5-A amplification in *D. discoideum* cells is under surveillance of a distinct RNAi pathway that requires AgnC function and that this control of mobile element expansion is at least in part overcome by CbfA, a factor derived from the retrotransposon’s host cell.

Results

CbfA regulates the expression of the Argonaute-like protein AgnC

Even though the accumulation of TRE5-A RNA in *D. discoideum* cells strictly depends on CbfA and this factor binds to the C-module of TRE5-A *in vitro*, it does not regulate the C-module’s promoter activity *in vivo* [21]. A probable explanation for this paradox could be that CbfA exerts an indirect effect by regulating an RNAi pathway that is involved in the control of TRE5-A expression. In concordance with a rather indirect and probably broader function of CbfA in the control of mobile elements, including TRE5-A, the re-evaluation of previously obtained mRNA-seq data [28] suggested a considerable amount of deregulation of transposable elements in the CbfA-depleted mutant JH.D compared to the parental strain AX2 (Fig. 1). Typically the differential expression of mobile elements between AX2 and JH.D cells was highly variable among different cell cultures and could not be unequivocally verified by quantitative RT-PCR. Nevertheless, this observation strengthened the hypothesis that the regulation of steady-state levels of TRE5-A RNA may not be directly regulated by CbfA by binding to the C-module, but rather be the result of CbfA regulating an RNAi pathway involved in the regulation of TRE5-A.

Following this hypothesis we used previously obtained mRNA-seq data [28] to determine differential expression of putative RNAi components between the CbfA mutant JH.D and parent AX2 cells. The Argonaute genes *agnC* and *agnE* were 228-fold and a 2.7-fold, respectively, overexpressed in JH.D cells (Fig. 2). The genes coding for Argonaute proteins AgnA and AgnB and the RdRP RrpC were slightly underexpressed in the JH.D mutant cells, whereas expression of the genes coding for the

Fig. 1 Expression of mobile elements in the CbfA underexpressing mutant JH.D. Expression data are derived from a previous RNA-seq analysis [28]. RPKM values (reads per kb of mRNA and standardized to 1 million reads) were obtained for the indicated mobile elements and calculated as ratio of JH.D versus AX2 and are shown as “fold change” of expression, meaning that values >1 represent overexpression of genes in JH.D. Values are means from three independent cultures \pm SD. * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$, relative to control AX2 cells (Student’s t-test). Black bars indicate non-LTR retrotransposons, grey bars indicate LTR retrotransposons (including the tyrosine recombinase retrotransposon DIRS-1), and white bars indicate putative DNA transposons

RdRPs *rrpA* and *rrpB* were unaffected by CbfA depletion (Fig. 2). RNA-seq also revealed normal expression of the genes coding for the two Dicer-like proteins of *D. discoideum*, *drnA* and *drnB*, in the CbfA mutant (Fig. 2). To confirm the RNA-seq data, we determined the expression the Dicer genes, the three RdRPs, and the five Argonaute genes by qRT-PCR. For these measurements we combined three RNA samples used in the previous RNA-seq experiment with RNA preparations from three additional independent cultures. The data were consistent in all six biological replicates and are presented in Fig. 2. The strong overexpression of *agnC* in the CbfA mutant was confirmed (257-fold, $p < 0.01$, Student’s t-test). The weak overexpression of *agnE* seen in RNA-seq could not be verified by qRT-PCR at a statistically significant level (4.3-fold overexpression; $p = 0.17$), although the trend to *agnE* overexpression in JH.D was reproduced (Fig. 2). The weak but highly significant underexpression of *agnA* in the JH.D mutant observed by RNA-seq (2.1-fold; $p < 0.001$) was confirmed by qRT-PCR (3.6-fold; $p < 0.01$), whereas results for *agnB* were inconclusive (Fig. 2).

CbfA can be divided into an amino-terminal part containing a “carboxy-terminal jumonji domain” and two zinc

Fig. 2 Expression of RNAi components in CbfA mutant JH.D cells. Expression of Dicer-like proteins (*drnA*, *drnB*), RdRPs (*rrpA*-*C*) and Argonaute genes (*agnA*-*E*) was analyzed by RNA-seq (gray bars, $n = 3$) in wild-type AX2 and CbfA-mutant JH.D cells from three independent cultures [28]. These three RNA samples, and RNA from three additional independent cultures, were analyzed by qRT-PCR (black bars, $n = 6$). Data are shown as fold change of expression with values >1 meaning that expression in the mutant cells was higher than in the control cells. Values are means \pm SD from three and six independent cultures, respectively. ** $p < 0.01$, *** $p < 0.001$, relative to wild-type AX2 cells (Student's t-test)

finger-like motifs, as well as a carboxy-terminal domain (CbfA-CTD) that contains a DNA-binding AT hook motif (Fig. 3a). We have previously determined that the CbfA-CTD is able to mediate most of CbfA's gene-regulatory activity without requiring the rest of the CbfA protein [28] and it also completely restores TRE5-A expression in JH.D cells [21]. We wanted to evaluate whether the aberrant expression of *agnC* and *agnE* in JH.D cells was reversed by expression of CbfA in the mutant. To this end, we expressed either full-length CbfA or a GFP fusion to CbfA-CTD in JH.D cells using multicopy expression plasmids as shown in Fig. 3b. To confirm functional expression of CbfA or CbfA-CTD in JH.D, we first determined TRE5-A expression (Additional file 1: Figure S1). TRE5-A underexpression was rescued to wild-type level by full-length CbfA and was even "over-complemented" by CbfA-CTD, which was likely due to overexpression of this protein relative to normal CbfA amounts present in AX2 cells (compare Fig. 3b). The overexpression of *agnC* in JH.D was reduced by full-length CbfA by 80 % ($p < 0.05$) and by CbfA-CTD by 92 % ($p < 0.05$) (Fig. 3c). This result was similar to previous RNA-seq data [28], which revealed 97 % reduction ($p < 0.001$) of *agnC* overexpression in response to the presence of CbfA-CTD [28]. Taken together, the data indicate that *agnC* is a genuine CbfA-regulated gene that requires CbfA-CTD for proper expression. The data argued for a role of AgnC in CbfA-dependent TRE5-A regulation because the accumulation of TRE5-A transcripts is also regulated by CbfA-CTD [21].

Expression of full-length CbfA in JH.D cells had only a minor effect on the observed overexpression of *agnE* in JH.D cells. Likewise, expression of CbfA-CTD in JH.D cells did not affect *agnE* overexpression in the CbfA mutant (Additional file 1: Figure S1). The latter results were consistent with previous RNA-seq data, which did not indicate an effect of CbfA-CTD on *agnE* expression [28]. Therefore, we cannot definitely conclude from our data that *agnE* is a genuine CbfA-regulated gene.

AgnC and AgnE downregulate TRE5-A expression

We performed qRT-PCR measurements to determine whether putative components of the *D. discoideum* RNAi machinery are involved in the silencing of TRE5-A expression. No significant changes of TRE5-A expression were determined when the genes coding for the Dicer-like protein DrnB or the RdRP proteins RrpA and RrpB were inactivated; however, we detected a mild but significant underexpression of TRE5-A in *rrpC* knockout cells (Fig. 4). Inactivation of *agnA* or *agnB* had no effect on TRE5-A expression (Fig. 4), whereas a 4.3- and 5.9-fold overexpression of TRE5-A was observed in knockout mutants of *agnC* and *agnE*, respectively (Fig. 4). Overexpression of TRE5-A in *agnC* and *agnE* knockout strains was completely reversed when AgnC or AgnE was expressed from a multicopy plasmid in the respective knockout mutant (Fig. 4), suggesting that both AgnC and AgnE contribute to TRE5-A regulation.

The role of AgnC and AgnE in the suppression of the TRE5-A population could be analyzed in more detail if the corresponding genes would be overexpressed in a wild-type background, i.e., in a strain with normal CbfA activity. This was an important consideration because previous data indicated that CbfA may have functions in TRE5-A retrotransposition beyond the regulation of TRE5-A RNA levels in supporting the integration process upstream of tRNA genes [21]. Usually, overexpression of proteins in wild-type cells is facilitated by transforming cells with expression plasmids. We assumed that this would be a suboptimal strategy for our experiments because transformants would contain insertions of multicopy plasmids at random genomic positions that could compromise the subsequent determination of retrotransposition activity of the TRE5-A population using the TRE trap assay (see below). With this consideration in mind, we decided to generate gene activation (GA) strains in which the endogenous promoter of either *agnC* or *agnE* was replaced by the strong *actin15* promoter (*act15P*) by

2016-fold excess *agnC* mRNA compared to AX2 cells. Yet the *agnC*^{GA} mutants had no obvious phenotype during growth and multicellular development. Expression of the *agnC*-upstream gene DDB_G0271884 was not affected by the homologous recombination yielding the *agnC*^{GA} strains (Fig. 5b). Semi-quantitative RT-PCR revealed that the TRE5-A steady-state transcript level in the *agnC*^{GA} mutants dropped sharply and was even more lower than in JH.D cells (Fig. 5b). This was confirmed by qRT-PCR, which suggested 24- to 45-fold lower expression of the TRE5-A ORF1 transcript in *agnC*^{GA} mutants than in wild-type cells, compared to a 4-fold decrease seen in JH.D cells (Fig. 5c). The data suggested that AgnC is directly involved in suppressing TRE5-A transcripts in *D. discoideum* cells.

Strains overexpressing the *agnE* gene in the AX2 background were constructed by employing the gene activation strategy as outlined in Additional file 1: Figure S2. Apparently overexpression of AgnE in the recovered *agnE*^{GA} strains resulted in an average of 2.3-fold underexpression of TRE5-A in four strains tested, thus confirming that AgnE may be involved in TRE5-A suppression.

AgnC is a suppressor of TRE5-A retrotransposition

It seemed plausible that silencing of TRE5-A expression would diminish retrotransposition of the TRE5-A population in the *agnC* and *agnE* overexpressor strains. To directly measure the retrotransposition activity of the cellular TRE5-A population, we set up a previously described “TRE trap” in vivo retrotransposition assay [18, 19] in *agnC^{GA}* cells. The TRE trap is based on a modified *pyr56* gene (*TRE^{trap}*) that codes for UMP synthase (Fig. 6). The *TRE^{trap}* gene contains an intron into which a *Val^{LAC}* tRNA gene was inserted as target for TRE5-A integrations. After transformation of the *TRE^{trap}* gene into *ura⁻* cells, the transformants present a *ura⁺* phenotype due to the expression of functional UMP synthase from the *TRE^{trap}* gene (with the intron including the tRNA gene being spliced out); however, the cells are prone to mutations in the *TRE^{trap}* gene by integration of cellular TRE5-A elements upstream of the embedded tRNA gene. Cells affected by TRE5-A integration into the *TRE^{trap}* gene can no longer splice out the intron and are converted to the *ura⁻* phenotype; they can be recovered after clonal growth in medium complemented with 5-fluoroorotic

acid (5-FOA) and uracil. In previous studies, approximately 100 insertions into the TRE trap were analyzed for integration by mobile elements [18, 19]. The data revealed that ~1 % of recovered *ura⁻* clones had spontaneous loss-of-function mutations of the *TRE^{trap}* gene, whereas ~99 % of the clones carried a TRE5-A element. No insertions of other members of the tRNA gene-specific TRE retrotransposon family were detected in this assay, suggesting that they amplify at a very low rate. Thus, the number of clones obtained in the TRE trap assay is an estimate of the TRE5-A retrotransposition activity in *D. discoideum* cells [18, 19].

In the experiments described above, AX2 was the parent strain for the generation of *agnC^{GA}* and *agnE^{GA}* mutants because we wanted to be able to directly compare them to JH.D cells, which were also derived from AX2. Because no suitable uracil-auxotrophic AX2 mutant was available, we reproduced *agnC^{GA}* mutants in the *ura⁻* strain DH1, which is an AX3 derivative [30]. As shown in Fig. 7a, overexpression of *agnC* in the recovered DH1[*agnC^{GA}*] strains was comparable to AX2[*agnC^{GA}*] cells. Likewise, TRE5-A ORF1 expression was suppressed in DH1[*agnC^{GA}*] strains, albeit at somewhat lower efficacy as in AX2[*agnC^{GA}*] cells. qRT-PCR revealed that TRE5-A expression in the particular DH1[*agnC^{GA}*] strain that we subsequently used to determine TRE5-A retrotransposition was 7.7-fold lower than in the parental DH1 strain. This DH1[*agnC^{GA}*] strain was transformed with plasmids carrying either the empty TRE trap (i.e., no tRNA gene inserted in the trap) or the *TRE^{trap}* gene, which contained a *Val^{LAC}* tRNA gene as bait for TRE5-A integrations. Five plates, each containing 10^7 cells, were cultured in minimal medium supplemented with 5-FOA and uracil until clones appeared. As the positive control, the TRE5-A retrotransposition frequency in DH1[*TRE^{trap}*] cells was determined at 2.03×10^{-5} , whereas it was $<0.01 \times 10^{-5}$ in DH1[*TRE^{trap}*] cells in which the *Val^{LAC}* tRNA gene was omitted as the negative control. In two independently recovered DH1[*agnC^{GA}/TRE^{trap}*] strains, TRE5-A retrotransposition activity was determined at 0.14×10^{-5} and 0.05×10^{-5} , representing a more than 90 % drop retrotransposition in the *agnC* overexpressing cells compared to control cells ($p < 0.001$, Student's t-test) (Fig. 7b). These data indicate that AgnC controls the amplification of TRE5-A elements in *D. discoideum* cells by limiting the accumulation of retrotransposon-derived RNA.

Although we were able to establish *agnE^{GA}* strains in the DH1 background, we could not recover viable cells after transformation of the *TRE^{trap}* gene into these cells. Therefore, we were unable to determine the retrotransposition activity of the TRE5-A population under these conditions. Thus, it remains elusive at this point whether the moderate downregulation of

TRE5-A transcripts in *agnE^{GA}* strains correlates with an appreciable suppression of the retrotransposition activity of the TRE5-A population.

Discussion

AgnC and AgnE act in RNAi pathways to suppress TRE5-A retrotransposition

Because the TRE5-A element produces both plus- and minus-strand RNA, we assumed that the retrotransposition frequency of the TRE5-A population may be under surveillance by the cellular RNAi machinery. In this study, we provide evidence to support this assumption. Genetic inactivation of either AgnC or AgnE resulted in overexpression of TRE5-A, suggesting that both proteins have functions in TRE5-A regulation in which the loss of one cannot be compensated for by expression of the other. The *D. discoideum* Argonaute proteins are a part of the PIWI subfamily of Argonaute proteins. They all have divergent amino-terminal domains, but possess conserved PAZ and PIWI domains including an intact DEDH catalytic tetrad and probably possess slicer activity. One model to explain TRE5-A silencing is the generation of PIWI-interacting RNAs (piRNAs) by AgnC and AgnE in a ping-pong piRNA replication mechanism typical for PIWI proteins [31]. This model is intuitive given that piRNAs are often generated from long single-stranded RNA precursors produced from transposable elements, such as the minus strand RNA of TRE5-A. However, piRNA are usually 23–30 nt long [31, 32], which contradicts results from a previous deep sequencing of small RNA libraries which revealed the formation of ~21 nt siRNAs from TRE5-A elements at a very low level (0.05 % of total small RNAs) in growing *D. discoideum* cells [15].

The silencing of the retrotransposon DIRS-1 is a model to study RNAi pathways in *D. discoideum* [14, 15, 17, 22]. Previous deep sequencing of small RNAs revealed high levels of DIRS-1-derived ~21 nt siRNAs [15] that add up to 20 % of all small RNAs detected in *D. discoideum* cells [17]. The difference in the amount of ~21 nt siRNAs derived from DIRS-1 and TRE5-A may be interpreted as the less efficient dsRNA formation from TRE5-A RNA compared to DIRS-1 RNA. DIRS-1 silencing is enhanced by the RdRP RrpC that synthesizes new DIRS-1 dsRNA that can be diced into secondary siRNAs [16]. This amplification step may be missing in the RNAi pathway that controls TRE5-A expression, because TRE5-A transcripts were not stabilized in RdRP-deficient mutants. The Dicer homolog DrnB, which is mainly required for miRNA formation in *D. discoideum* [15], is apparently not involved in the regulation of DIRS-1 RNA levels [17] and it seems to be also dispensable in the process of TRE5-A regulation (Fig. 4). Thus, the RNAi pathways that regulate DIRS-1 and TRE5-A may overlap at the stage of primary siRNA formation, presumably involving the Dicer homolog DrnA, but use different RISCs that contain either AgnA for DIRS-1 silencing [22] or AgnC/AgnE for TRE5-A suppression.

CbfA abrogates TRE5-A suppression by repressing AgnC

The C-module at the 3' end of the TRE5-A element has promoter activity that is responsible for the production of minus-strand RNA by the element [20]. CbfA was originally identified as a "C-module-binding factor" because it binds to the C-module of TRE5-A in vitro [24], but it does not regulate the C-module promoter activity in vivo [21]. Considering that CbfA regulates more than 1000 genes of the *D. discoideum* genome, the present data suggest that the observations of in vitro binding of CbfA to the C-module and in vivo regulation of steady-state levels of TRE5-A transcripts by CbfA are purely coincidental. Together with the data obtained in this study, we propose instead that the accumulation of TRE5-A transcripts in *D. discoideum* cells is indirect and a result of the CbfA-mediated suppression of a post-transcriptional pathway involving AgnC. This assumption is supported by the observation that both the plus- and minus-strand RNA of TRE5-A simultaneously vanish upon removal of CbfA from cells, but reappear when CbfA is re-introduced into CbfA-underexpressing cells [21]. In a previous mRNA-seq experiment comparing gene expression in JH.D with wild-type cells [28] we detected underexpression of putative DNA transposons such as DDT-A and DDT-S, the long-terminal repeat (LTR) retrotransposon Skipper, and the non-LTR retrotransposon TRE5-B (see Fig. 1). RNA-seq also predicted overexpression of some mobile elements in the absence of CbfA such as the tyrosine recombinase retrotransposon DIRS-1, the LTR retrotransposon DGLT-A, and the non-LTR retrotransposons TRE3-C and TRE3-D. However, differential expression of the mentioned mobile elements in JH.D cells could not be unequivocally confirmed by qRT-PCR. This was obviously due to high biological variation between independent cultures that was never observed when analyzing the expression of coding genes (i.e., Fig. 2) and the reason for this phenomenon remains elusive. At least the overexpression of DIRS-1 in JH.D cells could be explained by the weak, but reproducible overexpression of the genes *rrpC* and *agnA* (Fig. 2), which were both shown to be involved in the downregulation of DIRS-1 [22]. Thus, DIRS-1 and TRE5-A may be suppressed by different RNAi pathways and are affected indirectly by CbfA's broad-ranging gene-regulatory activity. Unfortunately, a high variability of mobile element expression among biological replicates was also observed when analyzing either *agnC* knockout or *agnC* overexpressor cells. Therefore, we are unable at this point to predict whether other mobile elements are regulated by the same AgnC-involving RNAi pathway that controls TRE5-A retrotransposition.

TRE5-A belongs to a family comprising seven tRNA gene-targeting retrotransposons in *D. discoideum* cells. The TRE5-A and TRE5-B elements are closely related

and share a common ancestor, but only TRE5-A was amplified to a high copy number rather late in the evolution of this species [12]. It is puzzling that TRE5-A amplification in *D. discoideum* was apparently accelerated after the acquisition of the C-module (i.e., an antisense promoter) and after the split from its common ancestor with the TRE5-B element that lacks a C-module. Intuitively, the incorporation of an antisense promoter into a mobile element should make it vulnerable to silencing by RNAi-related mechanisms and thus prevent its amplification. Because the C-module was most likely acquired by 3'-transduction, a process not uncommon in this class of retrotransposons [33], the question of what advantage the element may have gained by incorporating an antisense promoter at its 3' end remains. Did *D. discoideum* cells gain a selective advantage from TRE5-A expansion? The release of TRE5-A from RNAi surveillance by a regulated process involving a host-encoded factor such as CbfA may have evolved because it could be used for cellular purposes such as enhancing genome flexibility. Alternatively, TRE5-A release from suppression by RNAi may have been incidentally caused by adaptation to evolutionary pressure forcing alterations in AgnC-mediated posttranscriptional regulation that are unrelated to transposon suppression. It is unknown under which conditions the repression of *agnC* by CbfA would be released or for which functions AgnC would be required; at least, it seems to be unrelated to the multicellular development of *D. discoideum* because *agnC* is barely upregulated during development [34] and neither *agnC* knockouts nor *agnC* overexpressor display a developmental phenotype. Repression of AgnC by CbfA may provide an efficient way to respond to changes in particular environmental conditions that require specialized functions of this Argonaute protein. Even if this mode of gene regulation by CbfA would come at the cost of TRE5-A amplification, it is reasonably tolerable because TRE5-A's targeted integration to regions upstream of tRNA genes would largely prevent insertion mutagenesis of the genome.

Whereas RNAi may have been developed to restrict mobile element expansion in *D. discoideum* as in other eukaryotes, as exemplified by DIRS-1 silencing, our study shows an intriguing example of a transposable element that is under surveillance by the cellular RNAi machinery, but the control of which can be overcome by suppression of a distinct RNAi pathway by a host factor.

Conclusions

The social amoeba *D. discoideum* has a compact and haploid genome that requires tight control of mobile element activity to maintain genome stability. The non-long terminal repeat retrotransposon TRE5-A actively amplifies in the genome of *D. discoideum* even though

the element should be vulnerable to posttranscriptional silencing due to the production of antisense RNA from an element-internal promoter. The host-encoded factor CbfA has global gene-regulatory functions in *D. discoideum* that include the suppression of the Argonaute-like proteins AgnC and AgnE. Whereas TRE5-A transcripts were found to accumulate in mutants lacking AgnC or AgnE, expression and retrotransposition of the element vanished in AgnC and AgnE overexpressing cells. These observations suggest that TRE5-A amplification is under surveillance by an RNAi pathway that involves AgnC and AgnE and that this control is at least partially overcome by the activity of CbfA. This unusual regulation of mobile element activity by a host factor most likely had a profound effect on genome evolution in *D. discoideum*.

Methods

Strains and plasmids

The CbfA-depleted mutant JH.D and the plasmids used for the expression of full-length CbfA and the GFP-tagged carboxy-terminal domain of CbfA (CbfA-CTD) have been previously described [21, 25]. *D. discoideum* strains harboring knockouts of RdRP genes *rrpA*, *rrpB*, and *rrpC* were described by Wiegand & Hammann [16]. Knockout strains of *agnA* and *agnB* were described elsewhere [22]. The *drnB*⁻ strain was described in Avesson et al., 2012 [35]. Knockout mutants of *agnC* and *agnE* as well as plasmids allowing for the expression of TAP-tagged AgnC and AgnE will be described in a separate publication (F.S. et al., manuscript in preparation).

Construction of gene activation mutants

The *D. discoideum* expression vector pDM326 [36] contains a blasticidin resistance cassette driven by the *act6* promoter and an upstream *act15* promoter in opposite direction for the expression of transgenes. A DNA fragment containing both the blasticidin cassette and the *act15* promoter was isolated from pDM326 by digestion with BamHI and BglIII. The DNA fragment was inserted into the BamHI site of pGEM7Zf(-) (Promega), such that the former BglIII site was placed next to the HindIII site of the pGEM vector to generate pGEM-GA. To generate the *agnC*^{GA} vector, the “BamHI arm” covering the entire coding sequence of the gene DDB_G0271884, which shares its upstream region with *agnC*, was amplified including 273 bp of residual upstream sequence and inserted into the BamHI site of pGEM-GA. The “HindIII arm” was generated by amplification of nucleotides 1–1166 of the *agnC* gene including its authentic translation start codon. The pGEM-agnC-GA plasmid was linearized and transformed into *D. discoideum* AX2 or DH1 cells and transformants were selected in HL5 medium (Formedium, Hunstanton, UK) containing 6 µg/ml blasticidin (Life Technologies, Carlsbad,

USA) [37]. From such clones genomic DNA was isolated and screened by PCR for insertion of the GA cassette at the targeted locus using one primer specific for the blasticidin resistance gene and a second primer that hybridized outside of the DNA sequences covered by the HindIII arm. RT-PCR was used to confirm that the expression of the *agnC*-upstream gene DDB_G0271884 was not affected by insertion of the GA cassette.

Reverse transcription-PCR

Total RNA was prepared from frozen cell pellets and RT-PCR was done as described previously [21]. In quantitative RT-PCR gene expression levels were standardized to the gene coding for catalase (*catA*). The following qRT-PCR primers were used: *rrpA*-01, GAA CGTCAAGAAGCTTGGTAAATGTATC; *rrpA*-02, TA ACCTACAGTTTGTAAAC CGAATGTTTAC; *rrpB*-01, GAACGTCAAGAAGCTTGGTAAATGTATAA; *rrpB*-02, GTGGATAACCTTTAGTTTTTAACCAAAC; *rrpC*-01, GGTGTTTATAGTAAAAAAGAATCATTC; *rrpC*-02, CAACTATCCAAGAATTTATGAACATTTAC; *agnA*-01, GCCGAAACTCCTTCTTCTTGGGGTAC; *agnA*-02, GT TCATCCAATAAGACATGGTAATGAG; *agnB*-01, GTG ATGGTGTGGTGATGGTATGTTAG; *agnB*-02, CTTG GTAATCCTGATCAAGGTGTTGTTG; *agnC*-03, GTG CACTTTTATGAGAGATTGGCATAAC; *agnC*-04, GT ACATGATAATGAGTTGGATTTGTAG; *agnD*-01, CA TCATATTAATAGTCGTTTACCAGAG; *agnD*-02, GT ACCAATCCACCCAATGGTACAATGG; *agnE*-03, GA GCATAATTACAAGGAGCAGGTGTTTC; *agnE*-04, CA GTGCTAACCATTGTACCATTGGGTG; *catA*-01, GT TTCGCTGCTCGTCAACCATAACAATC; *catA*-02, GC ACGAAGCTTGAATTTCTTTGATGGTG; *gpdA*-01, GG TTGTCCCAATTGGTATTAATGG; *gpdA*-02, CCGTG GGTTGAATCATATTTGAAC; TRE5-A ORF1 Rep-108, GTCATAAACATCAATCCGAACCAGAC; TRE5-A ORF1 Rep-109, GTTAGATTGTCTAGTTCAATGATAGTGTC; TRE5-A ORF2 Rep-75, GACTGTTCAAGTGATAATAA CC; TRE5-A ORF2 Rep-176, CTCGAGTTAAAGGAAGA TTGCTCTTGAATC; DDB_G0271884-01, GAGTTGGC CAAATTAGTTAAGCAATTG; DDB_G0271884-02, CC TTGTTCAACCCAAGAGAAAATTTCTG.

TRE trap retrotransposition assay

The TRE trap is an in vivo retrotransposition assay that measures the activity of the cellular TRE5-A population. It was essentially performed as described previously [21]. The TRE trap consists of the complete *pyr56* gene modified to contain a functional intron into which a *Val*^{LIAC} bait tRNA gene was inserted. This gene is referred to as the *TRE*^{trap} gene. After transformation into *D. discoideum* DH1 cells, *ura*⁺ cells harboring chromosomal integrations of the *TRE*^{trap} gene were recovered by cultivation in FM medium without supplements. After integration of a

TRE5-A element into the trap, the *TRE^{trap}* gene is disrupted and no functional UMP synthase is expressed. Thus, affected cells were converted to the *ura⁻* phenotype and gained resistance to the drug 5-fluoroorotic acid (5-FOA). In a typical retrotransposition assay, 5 plates each containing 10^7 cells were prepared, and cells were cultured in FM medium containing 150 $\mu\text{g/ml}$ 5-FOA and 20 $\mu\text{g/ml}$ uracil. Clones that arose were counted, and the data presented are the means from 5 plates \pm SD.

Western blots

D. discoideum cells were washed in phosphate buffer and stored as frozen pellets of 2×10^7 cells at -80°C . SDS/polyacrylamide gel electrophoresis of whole-cell extract proteins and western blotting were done as described [38]. We used monoclonal antibody 7 F3 to detect Cbfa and a polyclonal antiserum to detect actin8 [38].

Additional data files

The following additional data are available with the online version of this paper. Additional file 1: Figure S1 shows the functional complementation of strain JH.D with Cbfa or its carboxy-terminal domain with respect to TRE5-A and *agnE* expression. Additional file 1: Figure S2 illustrates the construction of *agnE^{GA}* mutants and shows the expression of TRE5-A in these mutants.

Additional file

Additional file 1: Figure S1. Functional complementation of strain JH.D with Cbfa or its isolated carboxy-terminal domain. RNA levels of retrotransposon TRE5-A (A) and *agnE* (B) were determined by qRT-PCR in JH.D cells, JH.D cells expressing full-length Cbfa, and JH.D cells expressing Cbfa-CTD. Expression levels in JH.D cells and JH.D transformants were compared to AX2 wild-type cells and are expressed as “fold change” of expression, meaning that values >1 represent overexpression of genes in the JH.D strains and a value of 1 would indicate complete reversion of the overexpression in JH.D cells. Values are means from six independent cultures \pm SD. $^{**}p < 0.01$, relative to control AX2 cells (Student's t-test). Note that TRE5-A is actually overexpressed in the JH.D[Cbfa-CTD] transformant, which is an effect of overexpression of Cbfa-CTD (see Fig. 2, main text). **Figure S2.** TRE5-A expression in *agnE^{GA}* mutants. (A) Construction of *agnE* “gene activation” mutants. The *agnE* locus on chromosome 5 is indicated by nucleotide positions. The gene activation cassette consisted of a hybrid *actin6/actin15* promoter (arrows indicate transcription direction). The BamHI arm contained a 1070 bp DNA fragment covering part of the coding sequence of gene DDB_G0289385. The HindIII arm contained 1080 bp of *agnE* coding sequence, including the original translation start site. After double-recombination of the *agnE^{GA}* vector with genomic DNA, the expression of *agnE* was driven by the *act15* promoter, whereas expression of the neighboring gene DDB_G0289385 was unaffected. (B) Semi-quantitative RT-PCR analysis of RNA from AX2, JH.D, and three independent *agnE^{GA}* mutants demonstrating overexpression of *agnE*, normal expression of the neighboring gene DDB_G0289385 and *gpdA* (loading control), and silencing of TRE5-A (ORF1 and ORF2 sequences). NTC: no template control. (C) Quantitative RT-PCR of TRE5-A (ORF1) expression on RNA from JH.D and four *agnE^{GA}* mutants. Expression levels were compared to AX2 cells and are expressed as fold change of expression, meaning that values <1 represent lower levels of TRE5-A in the mutants relative to wild-type AX2 cells. Data represent means from four independent cultures of the indicated strains \pm SD. (PDF 1033 kb)

7. Diskussion

In der *Dictyostelium-discoideum*-Mutante JH.D, in welcher der C-Modul-bindende Faktor A (CbfA) nur schwach exprimiert wird, zeigte sich eine deutliche Fehlregulation von Transposons (Abbildung 7.1).

Abb. 7.1: Darstellung der Transposonfehlregulation in der Mutante JH.D im Vergleich zum Wildtyp. Es wurden die RNA-Seq-Daten aus Manuskript 2 durch Mapping der *Reads* auf die Consensus-Sequenzen der dargestellten Transposons neu ausgewertet. Abgebildet ist der *fold change* der Transposonexpressionen JH.D/Wildtyp. Eine Expression von 1 entspräche der Wildtyp-Expression; Expressionen größer 1 entsprechen einer Überexpression in der Mutante. Weiße Balken: Non-LTR-Transposons; graue Balken: LTR-Transposons; schwarze Balken: DNA-Transposons. Ergebnisse stellen Mittelwerte von drei unabhängigen Kulturen dar \pm Standardabweichung. *: $p < 0,05$; **: $p < 0,01$; ***: $p < 0,001$, in Bezug zum WT (Student's T-Test). (Modifiziert nach Manuskript 4).

Eine mögliche Abhängigkeit der Regulation mobiler Elemente durch CbfA betrifft sowohl DNA-Transposons als auch die Retrotransposons aus *D. discoideum*, darunter auch TRE5-A und DIRS-1. TRE5-A ist dabei in JH.D unterexprimiert und DIRS-1 überexprimiert (Abb. 7.1). Beide Retrotransposons sind in *D. discoideum* bereits sehr gut charakterisiert und dienen in dieser Arbeit als Modelle für die Transposonregulation in *D. discoideum*. Im Fall von TRE5-A konnte bereits gezeigt werden, dass die Regulation dieses Retrotransposons in Abhängigkeit

von CbfA nicht durch eine Bindung von CbfA an die beiden vorhandenen Promotoren (A- und C-Modul) erfolgt (Bilzer et al., 2011). Dies bedeutet, dass die *In-vitro*-Bindung von CbfA an das C-Modul und die Regulation von TRE5-A nicht in einem kausalen Zusammenhang stehen. Daher wurde ein anderer, indirekter Regulationsweg vermutet. Von TRE5-A und DIRS-1 ist bekannt, dass *Sense*- und *Antisense*-Transkripte gebildet werden (Rosen et al., 1983; Zuker et al., 1983; Schumann et al., 1994; Wiegand et al., 2013). Diese Tatsache führte zu der Annahme, dass posttranskriptionelle Stilllegungsprozesse wie RNA-Interferenz (RNAi) an der Regulation dieser Retrotransposons beteiligt sein könnten. Warum das Fehlen des Transkriptionsregulators CbfA zu einer Fehlregulation der Transposons in *D. discoideum* führt, war bislang unklar und konnte in dieser Arbeit zum Teil aufgeklärt werden.

7.1 Beeinflussung der Expression von TRE5-A durch wirtseigenen Transkriptionsregulator

Wie schon in Abbildung 7.1 dargestellt und auch in früheren Arbeiten beobachtet (Beck, 2002), fällt die Transkriptmenge von TRE5-A drastisch ab, sobald CbfA wie im Stamm JH.D unterexprimiert ist. TRE5-A gehört zu den *tRNA gene-targeted retroelements* (TREs), den Non-LTR-Retrotransposons aus *D. discoideum*, welche Integrationsorte in definierten Abständen zu tRNA-Genen vorweisen (Glöckner et al., 2001; Winckler et al., 2005). CbfA bindet an das C-Modul von TRE5-A *in vitro* (Geier et al., 1996). Da es sich bei CbfA um einen zelleigenen generellen Transkriptionsregulator handelt (Lucas et al., 2009), wurde vermutet, dass CbfA als Wirtsfaktor die Expression der Transkripte von TRE5-A unterdrückt und somit eine Retrotransposition dieses Elements verhindert. Doch die Ergebnisse dieser Arbeit zeigen, dass diese Annahme falsch war und CbfA im Gegenteil die Akkumulation der TRE5-A-Transkripte und die Retrotransposition fördert (siehe Manuskript 1). So konnte im Stamm JH.D mit stark verminderter CbfA-Expression (Winckler et al., 2001) ein drastischer Abfall von sowohl *Sense*- als auch *Antisense*-RNA von TRE5-A detektiert werden. Dieser Effekt ließ sich in Komplementationsstudien mit Expression von rekombinantem CbfA beziehungsweise rekombinanter carboxyterminaler Domäne (CTD) von CbfA in JH.D revertieren. Somit konnte gezeigt werden, dass tatsächlich CbfA beziehungsweise auch allein die CTD von CbfA für die Transkriptakkumulation von TRE5-A nötig ist. Der Abfall der Transkripte ließ auf einen direkten Einfluss von CbfA auf die beiden Promotoren von TRE5-A für die Expression der RNAs schließen. Dies konnte jedoch widerlegt werden (siehe Manuskript 1). Da sowohl *Sense*- als auch *Antisense*-RNA von TRE5-A synthetisiert werden, stellen die TRE5-A-Transkripte ein mögliches Ziel für die posttranskriptionelle Regulation durch RNA-Interferenz-Prozesse (RNAi) dar. Beeinflusst CbfA eine oder mehrere

Komponenten der RNAi-Maschinerie in *D. discoideum* und fördert dadurch die Akkumulation der TRE5-A-Transkripte? Tatsächlich ergaben vergleichende RNA-Seq-Analysen zwischen Wildtyp und JH.D (siehe Manuskript 2) eine differentielle Expression dreier Argonauten-Proteine (Agn) und einer RNA-abhängigen RNA-Polymerase (Rrp) im CbfA schwach exprimierenden Stamm JH.D.

7.2 TRE5-A- und DIRS-1-Regulation über Komponenten der RNA-Interferenz (RNAi)

TRE5-A

Im Laufe der Untersuchungen zur Funktionsaufklärung von CbfA wurden RNA-Seq-Experimente durchgeführt. Deren Auswertung ergab, dass in der CbfA-Mutante JH.D *agnC* etwa 230-fach und *agnE* etwa 3-fach im Vergleich zum Wildtyp überexprimiert wird. Die anderen Argonauten-Proteine und die RNA-abhängigen RNA-Polymerasen sind in JH.D im Vergleich zum Wildtyp nicht überexprimiert. *agnA* und *rrpC* sind dagegen in JH.D schwächer exprimiert als im Wildtyp. Diese Ergebnisse konnten mit Hilfe von qRT-PCR-Experimenten bestätigt werden (Abbildung 7.2). Zusätzlich wurden siRNAs mit einer Länge von 20 bis 22 Nukleotiden entdeckt, die TRE5-A zugeordnet werden konnten (Hinas et al., 2007). Auch dies spricht für eine TRE5-A-Regulation durch RNAi-Prozesse. Es wurde daher überprüft, ob und welche Komponenten der RNAi-Maschinerie TRE5-A regulieren.

Abb. 7.2: Expression verschiedener RNAi-Komponenten im Vergleich JH.D- zu Wildtypzellen. Abgebildet ist der *fold change* der Expressionen JH.D/Wildtyp. Eine Expression von 1 entspräche der Wildtyp-Expression;

Expressionen größer 1 entsprechen einer Überexpression in der Mutante. Graue Balken: RNA-Seq dreier unabhängiger Kulturen von WT und JH.D, n = 3. Schwarze Balken: qRT-PCR der drei Kulturen der RNA-Seq und dreier zusätzlicher unabhängiger Kulturen, n = 6. Ergebnisse stellen Mittelwerte von drei bzw. sechs unabhängigen Kulturen dar \pm Standardabweichung. **p<0.01, ***p<0.001, # p = 0.17, in Bezug zum WT (Student's T-Test). (Modifiziert nach Manuskript 4).

Um testen zu können, ob Komponenten der RNAi-Maschinerie aus *D. discoideum* Einfluss auf TRE5-A haben, wurden in dieser Arbeit zunächst *Knockout*-Mutanten verschiedener RNAi-Komponenten mittels qRT-PCR auf die Expression von TRE5-A getestet. Und wie bereits vermutet, zeigten nur *agnC*- und *agnE*-Zellen eine deutliche Überexpression von TRE5-A (siehe Manuskript 4). Wurden im jeweiligen *Knockout*-Hintergrund *agnC* beziehungsweise *agnE* überexprimiert, so gleicht sich die TRE5-A-Expression in etwa dem Wildtypniveau an. *agnC* und *E* sind demnach tatsächlich an der Expressionsregulation von TRE5-A beteiligt. Die Ergebnisse wurden allerdings mit Hilfe des CbfA-Unterexpressionsstamms JH.D ermittelt. CbfA ist jedoch vermutlich auch für die Regulation der Retrotransposition beziehungsweise Integration von TRE5-A verantwortlich (siehe Abschnitt 7.4). Daher wurden *agnC* und *agnE* im Wildtyp überexprimiert. Dies hat den positiven Effekt, dass die CbfA-Expression nicht verändert ist. Gleichzeitig lässt sich überprüfen, ob die Überexpression von *agnC* und *agnE* zu einer Verringerung der TRE5-A-Expression führen.

Die Überexpression von *agnC* und *agnE* erfolgte durch Erzeugung der so genannten Genaktivierungsstämme (GA). Mit Hilfe homologer Rekombination wird der geneigene Promotor gegen einen konstitutiven Actin-15-Promotor ausgetauscht, wobei die umliegenden Genbereiche nicht verändert werden (Abbildung 7.3). Dies ist von Vorteil, da anschließend weitere Transformationen möglich sind. Und die sonst verwendeten Expressionsplasmide können zu vielen Insertionen an verschiedenen unbekannten Positionen im Genom führen, welche anormale Genexpressionen erzeugen und weiterführende Experimente verfälschen könnten (Windhof et al., 2013).

Abb. 7.3: Methode der Genaktivierung am Beispiel *agnC*. Dargestellt ist der genomische *agnC*-Lokus in *D. discoideum*. Durch homologe Rekombination von Genaktivierungsplasmid und genomischer DNA erfolgt die *agnC*-Expression durch den konstitutiv aktiven Actin15-Promotor. PCR: Polymerasekettenreaktion; B: BamHI-Schnittstelle; H: HindIII-Schnittstelle; bsr: Blastizidinresistenzkassette; Act6/15P: Actin6/Actin15-Promotor – Hybrid; Pfeile: Transkriptionsrichtung. (siehe Manuskript 4 für weitere Informationen).

Die GA-Stämme, welche entweder AgnC oder AgnE überexprimieren, zeigten eine signifikante Reduktion der TRE5-A-Transkripte. Im AgnC-GA-Stamm konnte ebenfalls eine signifikante Abnahme der Retrotranspositionsfrequenz von TRE5-A verzeichnet werden. Die Abnahme der Retrotransposition korreliert sehr gut mit der Abnahme der Transkriptmenge: AngC und AgnE werden vermutlich über die siRNAs von TRE5-A zu den Transkripten geführt und sorgen an dieser Stelle für die Degradation der Element-RNA. Dies führt wiederum dazu, dass keine TRE5-A-Proteine synthetisiert werden können, welche für die Transposition benötigt werden. Im Fall von TRE5-A konnte somit zum ersten Mal gezeigt werden, dass die Regulation dieses Retrotransposons über Komponenten des zelleigenen RNAi-Systems erfolgt.

DIRS-1

D. discoideum scheint verschiedene Strategien für die Regulation verschiedener Transposons entwickelt zu haben. So wird DIRS-1 von AgnA reguliert: In *agnA*⁻-Stämmen nimmt die Menge an DIRS1-siRNAs ab und DIRS-1-Transkripte können akkumulieren (Boesler et al., 2014). Auch ist die RNA-abhängige RNA-Polymerase RrpC an der DIRS-1-Regulation beteiligt, wie bei der Erzeugung sekundärer siRNAs, welche das Stilllegungssignal verstärken (siehe Manuskript 3). Darauf deuten auch die Ergebnisse der

erwähnten RNA-Seq-Experimente hin: Dort zeigte sich in JH.D eine Unterexpression von *agnA* und *rrpC* und eine gleichzeitige Überexpression von DIRS-1 (siehe Abb. 7.1 und 7.2). Rrps sind an der TRE5-A-Regulation nicht beteiligt (siehe Manuskript 4). Ein weiterer Unterschied zwischen beiden Transposons zeigt sich in der Menge der siRNAs. So existiert eine sehr hohe Anzahl von DIRS-1-siRNAs, die bis zu 20 % aller detektierbaren siRNAs in *D. discoideum* ausmachen, während die Menge von TRE5-A-generierter siRNAs nur 0,05 % beträgt (Hinas et al., 2007; Manuskript 3). Ausschließen kann man bei beiden Transposons eine Beteiligung des Dicer-Homologs DrnB an der siRNA-Produktion und der generellen Transposonregulation, da der vorhandene *Knockout*-Stamm nicht zu entsprechenden Ergebnissen wie veränderter siRNA-Menge oder Expression führt. Dies scheint folgerichtig, da DrnB in der Zelle in erster Linie an der Bildung von miRNAs beteiligt zu sein scheint (Avesson et al., 2012). Über die Funktion von DrnA, ebenfalls ein Dicer-Homolog, kann nur spekuliert werden, da bisher noch keine entsprechenden *Knockout*-Stämme vorhanden sind, um die Proteinfunktionen zu studieren. Vermutlich ist dieses Protein im Fall von TRE5-A und DIRS-1 für die Bildung der primären siRNAs nötig, um die nachfolgenden RNAi-Prozesse zu aktivieren.

Warum aber betreibt die Zelle im Fall von DIRS-1 einen vermeintlich höheren Aufwand, um die Akkumulation von Transkripten und damit Transposition von DIRS-1 zu verhindern? DIRS-1 ist mit 235 vorhandenen Kopien das in *D. discoideum* am häufigsten vorkommende Transposon (Glöckner et al., 2001; Eichinger et al., 2005). Die Transposition erfolgt stets in bereits vorhandene Kopien an jeweils einem Ende der Chromosomen, wo diese DIRS-1-Cluster wahrscheinlich die Centromere ausbilden (Eichinger et al., 2005; Glöckner und Heidel, 2009). Eine unkontrollierte Vermehrung von DIRS-1 und damit ständige Integration in die bereits vorhandenen Cluster würde vermutlich zu einer Instabilität der Centromere führen. Da Centromere für die exakte Aufteilung der Chromosomen auf die Schwesterzellen nötig sind, würde deren Instabilität schließlich in einer Instabilität des gesamten Genoms resultieren. Wird durch Stilllegung von DIRS-1 die Größe der Centromere selektioniert? Würde DIRS-1, wenn es an einer beliebigen Position auf den Chromosomen integriert, zu der Ausbildung einer neuen centromeren Region führen? Und reicht dafür ein Element oder wird eine bestimmte Menge an Elementen und anderen Sequenzen benötigt, wie das beispielsweise auch in *Zea mays* der Fall ist? Dort wird eine bestimmte Anzahl an transposablen Elementen benötigt, die eine Domäne ausbilden, welche für die Funktionalität der Centromere entscheidend ist (Jin et al., 2005). Dabei wird diese Domäne nicht nur von einem transposablen Element gebildet (Jin et al., 2005). Dies korreliert wiederum mit den Kenntnissen, dass in *D. discoideum* auch Skipper in centromere Bereiche integriert (Glöckner und Heidel, 2009). Die unkontrollierte Vermehrung von DIRS-1-Elementen wäre zusammenfassend vermutlich letal für die Zelle. TRE5-A dagegen integriert spezifisch in die

Nähe von tRNA-Genen (Marschalek et al., 1989; Hofmann et al., 1991; Marschalek et al., 1992), die vermutlich genomisch „sichere“ Integrationsorte darstellen.

7.3 Förderung der TRE5-A-Expression durch zelleigene Suppression von Komponenten des RNAi-Systems

Die Auswertung der RNA-Seq-Experimente ergab, dass CbfA die Argonauten-Proteine AgnC und AgnE supprimiert. Dies bedeutet, dass beide womöglich CbfA-abhängig reguliert werden. Es konnte gezeigt werden, dass beide Argonauten-Proteine die TRE5-A-Expression unterdrücken und AgnC auch die Retrotransposition von TRE5-A reduziert (siehe Manuskript 4). Ebenso fördert CbfA Expression und Retrotransposition von TRE5-A (siehe Manuskript 1). Im Laufe dieser Arbeit konnte gezeigt werden, dass beide Prozesse in direktem Zusammenhang stehen. So supprimiert CbfA die Argonauten-Proteine AgnC und AgnE und beeinflusst damit TRE5-A positiv, indem es die Funktion der RNAi-Maschinerie in der Regulation von TRE5-A unterdrückt.

An dieser Stelle muss erwähnt werden, dass die Regulation von AgnC und AgnE durch CbfA möglicherweise über verschiedene Wege erfolgt. Komplementationsstudien, in welchen rekombinantes CbfA oder rekombinante CTD von CbfA in JH.D exprimiert werden, führten nur im Fall von AgnC zu einer fast vollständigen Komplementation (siehe Manuskript 4). Im Fall von AgnE konnte keine statistisch signifikante Reduzierung der Überexpression durch CbfA ermittelt werden. Jedoch ist erwähnenswert, dass komplettes rekombinantes CbfA die *agnE*-Überexpression immerhin um 52 % senkt. Durch die CTD erfolgt keine Komplementation. An dieser Stelle kann spekuliert werden, ob die verschiedenen Proteindomänen von CbfA für diese unterschiedliche Regulation von AgnC und AgnE durch CbfA verantwortlich sind oder ob CbfA überhaupt an der AgnE-Regulation beteiligt ist.

Nach Betrachtung der Ergebnisse stellt sich die Frage, warum CbfA als ein zelleigener allgemeiner Transkriptionsregulator den AgnC/AgnE-abhängigen Weg des zelleigenen RNAi-Systems unterdrückt und somit TRE5-A-Expression und –Retrotransposition unterstützt. RNAi evolvierte womöglich als ein Abwehrprozess gegen Viren und Transposons und die ersten entdeckten siRNAs stammten von Viren (Hamilton und Baulcombe, 1999; Baulcombe, 2004). Viren haben einige Abwehrmechanismen entwickelt, die es ihnen ermöglichen, dass Wirts-RNAi-System zu umgehen beziehungsweise zu hemmen. So findet beispielsweise im Fall des *Flock house virus* aus *Drosophila melanogaster* die virale Replikation in Membranvesikeln statt und die Zwischenstufen sind dem RNAi-System somit nicht zugänglich (Miller et al., 2001; Kopek et al., 2007; Venter und Schneemann, 2008). Auch

kodieren Viren für Suppressoren des RNAi-Systems, die zum Beispiel an dsRNA binden und Dicer-Proteine inhibieren (van Rij, 2006). Für Transposons beziehungsweise Retrotransposons sind solche Strategien nicht bekannt. Jedoch zeigen einige Studien in *Drosophila* und *Arabidopsis*, dass kleine RNAs (sRNA) von transposablen Elementen (TE) in der Lage sind, die Expression von Wirtsgenen zu beeinflussen und zwar durch partielle Sequenzübereinstimmungen zwischen TE-sRNA und mRNA des entsprechenden Wirtsgens (Rouget et al., 2010; McCue et al., 2013). In *Arabidopsis* konnte gezeigt werden, dass TEs damit in der Lage sind, Mechanismen zu supprimieren, die für die Stilllegung von TEs verantwortlich sind (McCue et al., 2013). Diese Abwehrmechanismen existieren allerdings unabhängig vom RNAi-System in *Arabidopsis* und können mit den in dieser Arbeit erhaltenen Daten schwer verglichen werden. In *D. discoideum* wird DIRS-1 erfolgreich durch RNAi supprimiert, die TRE5-A-Suppression durch RNAi jedoch durch CbfA unterbunden. So lässt sich spekulieren, ob TRE5-A in irgendeiner Form möglicherweise positive Effekte auf die Zelle hat. So ist in *Saccharomyces cerevisiae* kein RNAi-System detektierbar und der Verlust des RNAi-Systems scheint positiv für *S. cerevisiae* zu sein. So kann ein sogenanntes Killervirus von der Zelle beherbergt werden, welches dazu führt, dass Killer-positive Stämme das Wachstum Killer-negativer Stämme inhibieren, was zu einem klaren Vorteil führt (Welsh und Leibowitz, 1982; Billmyre et al., 2013). Durch Expression verschiedener RNAi-Komponenten wie Dicer- und Argonauten-Proteine in *S. cerevisiae* kann das RNAi-System erfolgreich aktiviert werden (Drinneberg et al., 2009). Der Effekt des Killervirus wird tatsächlich unterbunden, wenn das RNAi-System in *S. cerevisiae* aktiviert wird (Drinneberg et al., 2009). Daher ist der Verlust von RNAi in *S. cerevisiae* für diesen Organismus von Vorteil. Da TRE5-A sehr spezifisch in die Nähe von tRNA-Genen integriert (Marschalek et al., 1989; Marschalek et al., 1992; Hofmann et al., 1991) und die Integration dort vermutlich nicht zu Veränderungen anderer Gene führt, wird dies womöglich keine Vorteile für die Zelle bringen. Daher ist es unwahrscheinlich, dass *D. discoideum* über CbfA TRE5-A positiv reguliert, um zum Beispiel Wachstums- und Entwicklungsvorteile zu erhalten. Allerdings könnte die erfolgreiche Retrotransposition von TRE5-A *D. discoideum* ein gewisses Maß an Genomflexibilität schaffen, die positiv für die Zelle wäre. Es wäre aber auch möglich, dass die positive Regulation von TRE5-A von der Zelle nur toleriert wird und die Kontrolle einer Komponente des RNAi-Systems aus vermutlich evolutionärem Druck das eigentliche Ziel der Zelle gewesen ist. Dadurch wurde die TRE5-A-Supprimierung durch RNAi aufgehoben. Da TRE5-A jedoch in „sichere“ Orte integriert, könnte dies von der Zelle in Maßen tolerierbar sein. Wieso sollte die Zelle aber die *agnC*-Expression auf geringem Niveau halten beziehungsweise warum besitzt dieses Gen einen starken Promotor, wenn es nicht exprimiert werden soll? Die Funktion von AgnC in *D. discoideum* ist bisher völlig unbekannt. Die Expression dieses Gens ist sowohl im vegetativen Stadium als auch während der

Entwicklung sehr gering (Stajdohar et al., 2015). *cbfA* hingegen wird stärker exprimiert und das Proteinlevel bleibt auch während der Entwicklung immer konstant (Stajdohar et al., 2015; unpublizierte Daten). Ob eine der Funktionen von CbfA die Supprimierung von *agnC* ist, bleibt trotzdem spekulativ. Es wäre entscheidend herauszufinden, welche Gene von *agnC* noch reguliert würden, wenn es nicht durch CbfA supprimiert wird. Vergleichende RNA-Seq-Analysen zwischen Wildtyp-, JH.D- und GA-*agnC*-Stämmen könnten darüber erste Informationen bieten. Ob CbfA *agnC* direkt durch Bindung an dessen Promotor reguliert, könnte wie in Manuskript 1 mit Hilfe eines Luciferase-Assays getestet werden. Besteht eine Regulation des *agnC*-Promotors, sollte ein signifikanter Unterschied in der Promotoraktivität zwischen Wildtyp und CbfA-unterexprimierendem Stamm JH.D detektierbar sein.

7.4 Beeinflussung der Retrotransposition von TRE5-A durch CbfA

CbfA beeinflusst die Retrotransposition von TRE5-A (siehe Manuskript 1), scheinbar noch auf anderem Weg ohne Regulation des RNAi-Systems. Die Verminderung der CbfA-Expression führt in JH.D zu einer Reduktion der Retrotransposition von TRE5-A um mehr als 90 %. Revertiert werden kann dieser Effekt ausschließlich durch Expression eines kompletten CbfA-Proteins. Die CTD von CbfA allein ist nicht befähigt, die verminderte Retrotransposition aufzuheben. Im Fall der TRE5-A-Expression dagegen ist die CTD allein ausreichend, um die Menge an TRE5-A-Transkripten zu erhöhen. Werden daher Expression und Retrotransposition von TRE5-A durch unterschiedliche Funktionen von CbfA reguliert? Da das komplette CbfA für die Retrotransposition nötig ist, lässt sich über eine Rolle der JmjC/ZF-Region in diesem Prozess spekulieren. CbfA ist ein DNA-bindendes Protein. Die TRE5-A-Transposition erfolgt jedoch vermutlich über die *target-primed reverse transcription* (Manuskript 1). Dabei entsteht jedoch keine dsDNA-Zwischenstufe, an die CbfA binden könnte (siehe Einleitung 3.2 und 3.2.1). Für die JmjC/ZF-Region wird eine Chromatiumgestaltende Funktion vermutet. Vielleicht führt eine durch CbfA regulierte Änderung des Chromatins an den tRNA-Genen als Integrationsort für TRE5-A zu einer vereinfachten Integration? Die zweite Zinkfinger-Region von CbfA besitzt Ähnlichkeit zum *Plant-homeo-domain*-Typ von Proteinen, die an Nukleosomen binden (Bienz, 2005; Sanchez und Zhou, 2011). Nukleosomen sind eine Organisationsstruktur des Chromatins. Dabei sind 147 bp DNA um ein Histon-Oktamer gewickelt (Richmond und Davey, 2003). Benachbarte Nukleosomen sind über einen 10 bis 50 bp langen DNA-Abschnitt miteinander verbunden (van Holde, 1989). tRNA-Gene sind in Regionen eingebettet, die nur eine geringe Nukleosomenverbreitung aufweisen, wahrscheinlich bedingt durch ihre essentielle Rolle in der Translation oder durch die Bindung der RNA-Polymerase III (Westenberger et al., 2009).

Außerdem ist bekannt, dass die Position von Nukleosomen durch DNA-bindende oder Chromatin-modellierende Proteine verändert werden kann (Vinayachandran et al., 2009). Kann demnach TRE5-A in eine Region zwischen Nukleosom und RNA-Polymerase III integrieren, weil CbfA womöglich die Position von Nukleosomen verändert? Die Nukleosomenposition und deren mögliche Änderung lassen sich experimentell nachweisen. Platt et al. haben 2013 in *D. discoideum* eine Methode etabliert, welche die genaue Position von Nukleosomen ermitteln kann: Dabei nutzt man die Micrococcal-Nuklease, die präzise in dem DNA-Abschnitt zwischen zwei Nukleosomen schneidet. Die freigesetzte, durch Nukleosomen geschützte DNA wird dann sequenziert und die erhaltenen Sequenzen aufs Genom kartiert. Mit Hilfe dieser Methode können Nukleosompositionen von Wildtyp und Mutanten verglichen werden. Sollte in JH.D eine zum Wildtyp veränderte Position der Nukleosomen an tRNA-Genen festgestellt werden, die auch rein durch die Integration von TRE5-A resultieren könnte, müsste geprüft werden, ob CbfA vielleicht an die Histone der Nukleosomen bindet. Dies könnte durch Hybridisierungsexperimente getestet werden. Zu allererst muss jedoch die Funktion der JmjC/ZF-Region von CbfA aufgeklärt werden, ob diese wirklich Chromatin-verändernde Aufgaben ausübt.

7.5 Funktion des Transkriptionsregulators CbfA

Entdeckt wurde der C-Modul-bindende Faktor A (CbfA) aus *D. discoideum* durch seine Bindung an das C-Modul des Retrotransposons TRE5-A *in vitro* (Geier et al., 1996). Um mehr über die Funktion von CbfA in der Zelle zu erfahren, wurde die CbfA-Suppressionsmutante JH.D erstellt, welche einen starken Entwicklungsdefekt aufweist (Winckler et al., 2001). Zunächst konnte mit *Microarray*-Analysen von Wildtyp und JH.D gezeigt werden, dass es sich bei diesem Protein um einen allgemeinen Transkriptionsregulator handelt, der in der Zelle viele verschiedene Gene positiv beziehungsweise negativ beeinflusst, wobei die CTD von CbfA als eine eigenständige genregulatorische Einheit dargestellt werden konnte (Lucas et al., 2009). Im Vergleich zu *Microarray*-Analysen können die *Next-Generation-Sequencing*-Technologien qualitativ und quantitativ eine weitaus höhere Sensitivität und Genauigkeit vorweisen. Um noch mehr über die Funktion von CbfA aussagen zu können, wurde in dieser Arbeit mittels RNA-Seq noch einmal die Genexpression von Wildtyp und JH.D verglichen. Mit Hilfe dieser Methode konnten 1030 CbfA-abhängige Gene identifiziert werden, welche mindestens eine dreifache Änderung der Genexpression im Vergleich zum Wildtyp aufweisen. Von diesen 1030 ermittelten Genen, waren nur 35 % auf dem *Microarray* vertreten. Dies zeigt die Notwendigkeit, die Analyse der Genexpression zur Ermittlung CbfA-abhängiger Gene mit

einer sensitiveren Methode zu wiederholen. Außerdem konnten die durch RNA-Seq erhaltenen Ergebnisse ausgewählter Gene mit Hilfe von quantitativer RT-PCR (qRT-PCR) bestätigt werden (siehe Manuskript 2). In diesen wurde die Expression verschiedener CbfA-abhängiger Gene in Zellkulturen gemessen, die unabhängig von denen sind, die für die RNA-Seq-Experimente genutzt wurden. Dies deutet auf eine gute Reproduzierbarkeit der erhaltenen Ergebnisse hin.

Die von Winckler und Kollegen 2001 ermittelten Phänotypen von JH.D wie verringerte Phagozytoserate und verlangsamtes Wachstum auf Bakterien lassen sich gut mit den ermittelten CbfA-abhängigen Genen in Beziehung bringen. So finden sich viele von CbfA positiv beeinflusste Gene, deren Proteine an Prozessen wie der Zusammensetzung von Phagozytosevesikeln, der Zusammensetzung des Zytoskeletts und allgemeinen zellulären Prozessen wie der Zellteilung beteiligt sind. Im Stamm JH.D, in welchem CbfA nur zu ca. 5 % exprimiert wird (Winckler et al., 2001), sind diese Gene unterexprimiert. Dies führt in der Folge zu den ermittelbaren Phänotypen. Allerdings liefern Gene von an Phagozytose beteiligten Proteinen in sowohl RNA-Seq, qRT-PCR als auch *Microarray*-Analysen verschiedene Ergebnisse. Da in jedem dieser Experimente verschiedene Kulturen verwendet wurden, scheint die Ursache in einer kulturabhängigen und sehr variablen Expression der betroffenen Gene zu liegen. Dies scheint plausibel, da auch der Prozess der Phagozytose in *D. discoideum* an sich ebenfalls zu einer schnellen Anpassung der Zellen und damit schnellen Änderung der Expression beteiligter Gene führt (Vogel et al., 1980; Bozzaro et al., 1987; Bracco et al., 1997; Balbo und Bazzaro, 2006; Sillo et al., 2008).

Auch wurde mittels RNA-Seq überprüft, welchen Einfluss eine konstitutive Expression der CTD von CbfA in JH.D auf die Genregulation hat. Es konnte gezeigt werden, dass ein erstaunlich hoher Anteil von CbfA beeinflussten Genen allein durch die CTD reguliert wird. So reagierten 85 % der positiv und 76,7 % der negativ von CbfA regulierten Gene auf die konstitutive Expression der CTD im JH.D-Hintergrund. Viele Gene sind demnach allein durch die CTD regulierbar, ohne dass der Rest des CbfA-Proteins dafür benötigt wird. Rund 70 % dieser CTD-regulierten Gene zeigten ein stärkeres Expressionslevel als im Wildtyp. Die Expression der entsprechenden Gene erfolgte demzufolge nicht nur wieder auf Wildtypniveau, wurde also komplementiert, sondern darüber hinaus. Da die konstitutiv exprimierte CTD in JH.D stark überexprimiert ist, was durch Western Blot bestätigt werden konnte (siehe Manuskript 4), handelt es sich dabei vermutlich um Überexpressionsartefakte.

7.5.1 Die Familie der C-Modul-bindender-Faktor-ähnlichen Proteine

In dieser Arbeit konnte eine neue Proteinfamilie definiert werden, die „C-Modul-bindender-Faktor-ähnlichen Proteine“. Sie ist definiert über eine konservierte JumonjiC/Zinkfinger 1/Zinkfinger 2 (JmjC/ZF1/ZF2)-Architektur mit variabler CTD. Dazu gehören die CbfA-Proteine der *Dictyosteliidae*, die CbfA-ähnlichen (CbfB-) Proteine der *Dictyosteliidae* und CbfA-ähnliche Proteine in Pilzen (Abbildung 7.4).

Abb. 7.4: Phylogenie der Cbf-ähnlichen Proteine und schematische Darstellung von CbfA und CbfB aus *D. discoideum* und DMM-1 aus *Neurospora*. Proteinsequenzen, die der JmjC/ZF-Region des *D. discoideum* CbfAs entsprechen wurden mit ClustalX 2.0 *aligned* und mit Tree-Puzzle 5.2 analysiert. Jmj: Jumonji-Domäne; ZF: Zinkfinger; NRD: Asparaginreiche Domäne; AT:AT-Haken; CTD: Carboxy-terminale Domäne. (siehe auch Manuskript 2 für weitere Informationen).

Die CbfA-ähnliche ZF-Region findet sich auch in Proteinen von Pflanzen und Tieren. Diese Proteine weisen dann aber nur ZF1 oder ZF2 auf. Ebenfalls konnte die typische Kombination der ZF mit einer JmjC-Domäne in Pflanzen und Tieren nicht gefunden werden. Jedoch findet sich diese Kombination in verschiedenen filamentösen Pilzen, in *Naegleria gruberi* und in *Acanthamoeba castellanii* und natürlich in allen vier Gruppen der *Dictyosteliidae* (Abb. 7.4). Phylogenetische Analysen dieser Region zeigten eine deutliche Trennung zwischen den CbfA-Proteinen der *Dictyosteliidae* und den CbfA-ähnlichen Proteinen (CbfB) der *Dictyosteliidae* und deren Orthologen in Pilzen. Die ZF2-Region ist in allen Organismen hoch konserviert. Dagegen zeigen sich in der ZF1-Region kleine Sequenzunterschiede. Diese führen zu der Annahme, dass es sich bei CbfB um die ursprüngliche Form des ZF1 handeln

könnte. So teilen sich ZF1-Regionen von CbfB-Proteinen aus *D. fasciculatum*, eine der am frühesten divergierte Art der *Dictyosteliidae*, und Pilzen ein Sequenzmotiv (siehe Manuskript 2). Eine kurze Verlängerung dieser Sequenz führte vermutlich zu einem Motiv, welches sich nur in CbfA-Proteinen der *Dictyosteliidae* finden lässt. So lässt sich zusammenfassen, dass sich die CbfA-ähnlichen Proteine vermutlich vor der Abspaltung der *Dictyosteliidae* entwickelt haben. In der Evolution der *Dictyosteliidae* entwickelten sich dann wahrscheinlich aus den CbfB-Proteinen die CbfA-Proteine.

Über die Funktionen dieser neu definierten Proteinfamilie der „C-Modul-bindender-Faktor-ähnliche Proteine“ lässt sich nur spekulieren. So ist DMM-1 (DNA Methylation Modulator-1) aus *Neurospora crassa* (Abbildung 7.4) an der Inhibierung einer Ausbreitung der Methylierung von Histon-3-Lysin-9 beteiligt (Honda et al., 2010). Dabei sind die JmjC- und ZF-Regionen für die Funktion des Proteins entscheidend und Deletionen und Mutationen in diesen Domänen führen zum Funktionsverlust (Honda et al., 2010). Die JmjC/ZF-Region von DMM-1 zeigt eine hohe Ähnlichkeit zu CbfA aus *D. discoideum*, die CTDs der beiden Proteine sind jedoch verschieden. Über eine Funktion der CTD von DMM-1 ist bislang nichts bekannt, nur dass sie für die Funktionsweise des Proteins nicht entscheidend ist (Honda et al., 2010). Ob die JmjC/ZF-Region von CbfA aus *D. discoideum* ebenfalls eine demethylierende Funktion ausübt, muss erst untersucht werden. Die hohe Sequenzähnlichkeit zu DMM-1 lässt aber darauf schließen. Ebenso dürften die anderen Proteine dieser Familie ähnliche Funktionen ausüben, da gerade die JmjC/ZF-Region eine hohe Konservierung aufweist.

7.5.2. CbfA-Proteine der *Dictyosteliidae*

Durch Strukturanalysen von CbfA mit CbfA-Proteinen anderer *Dictyosteliidae*-Arten konnte herausgefunden werden, dass die jeweiligen CTDs dieser Proteine innerhalb der *Dictyosteliidae* gut konserviert sind. Die *Dictyosteliidae* sind in den Gruppen 1 bis 4, aufgrund der Analyse der Sequenzen der kleinen Untereinheit der rRNA und dem Vergleich von α -Tubulin, eingruppiert (Schaap et al., 2006). *D. discoideum* wurde der Gruppe 4 zugeordnet. Die CTDs der CbfA-Proteine innerhalb der Gruppe 4 weisen eine Identität von bis zu 98 % auf. Verglichen mit den Gruppen 1, 2 und 3 weisen die CTDs der entsprechenden Arten noch Identitäten von mehr als 40 % auf. Des Weiteren sind die CbfA-CTDs dieser Gruppen verlängert, ohne dass diese Verlängerungen Homologien zueinander erkennen lassen. Um zu testen, ob diese Domänen auch funktionell ähnlich sind, wurde die CTD von *Polysphondylium pallidum* konstitutiv in JH.D (*D. discoideum*) exprimiert und die Änderungen

der Genexpression durch RNA-Seq ermittelt und mit der Expression der *D. discoideum*-CTD in JH.D verglichen. *P. pallidum* gehört der Gruppe 2 an und divergierte damit schon frühzeitig von den Gruppe-4-Arten wie *D. discoideum*. Erstaunlicherweise wurden dennoch 73,3 % der CbfA-aktivierten und 51,4 % der von CbfA negativ regulierten Gene von der artfremden CTD wiederhergestellt. Dies weist nicht nur auf eine strukturelle Konservierung, sondern viel mehr auch auf eine funktionelle Konservierung der CTDs der CbfA-Proteine innerhalb der *Dictyosteliidae* hin. Dies ist besonders bemerkenswert im Hinblick auf die 600 Millionen Jahre Evolutionszeit der *Dictyosteliidae* (Glöckner und Noegel, 2013). Erwähnenswert ist außerdem, dass *D. discoideum* einen höheren A/T-Gehalt im Genom aufweist als *P. pallidum* (Heidel et al., 2011). Die CTD von *D. discoideum* benötigt die Bindung an A/T-reiche Sequenzen *in vitro* und *in vivo*, um seine genregulatorische Funktion auszuführen (Horn et al., 1999; Lucas et al., 2006). Umso bemerkenswerter ist die Tatsache, dass die *P. pallidum*-CTD die Expression einer derart hohen Anzahl von Genen im Genom von *D. discoideum* wiederherstellen kann.

Innerhalb der *Dictyosteliidae* sind die CTDs der CbfA-Proteine konserviert. Jedoch sind die CTDs der CbfB-Proteine (CbfA-ähnliche) der *Dictyosteliidae* verlängert, und sie zeigen keinerlei Ähnlichkeit zueinander. Dies lässt in Zusammenhang mit der Konservierung der JmjC/ZF-Region vermuten, dass sich diese CTDs evolutionär schneller entwickelt haben, vermutlich unter Art-spezifischem Anpassungsdruck.

Die Unterschiede zwischen den CbfA- und CbfB-Proteinen der *Dictyosteliidae* führen vermutlich zu Spezifikationen in ihren Proteinfunktionen. So kann im *D. discoideum*-Stamm JH.D CbfB nicht die ausgefallenen Funktionen von CbfA übernehmen, sonst könnte sich ein so ausgeprägter Phänotyp wie in JH.D vermutlich nicht ausbilden. Welche Unterschiede in den Funktionen beider Proteine aber genau liegen, muss noch weiter untersucht werden. Bisher war die Stilllegung des *cbfB*-Gens in JH.D noch nicht möglich, was jedoch Voraussetzung für die entsprechenden Experimente ist.

7.6 Ausblick

Die posttranskriptionelle Regulation von TRE5-A konnte in dieser Arbeit soweit aufgeklärt werden, dass die Argonauten-Proteine AgnC und AgnE als Komponenten des RNAi-Systems in *D. discoideum* TRE5-A regulieren. Dabei bleibt weiter zu klären, ob das Dicer-Protein DrnA für die Synthese der siRNAs von TRE5-A verantwortlich ist. Die Herstellung eines entsprechenden *drnA*-Stammes wäre für die Beantwortung dieser Fragestellung hilfreich. Auch Nachweise der Bindung von siRNA von TRE5-A in RISC-Komplexe mit

entweder AgnC oder AgnE als Kernkomponente und der Beweis des Abbaus von TRE5-A-RNA durch RISC wären für die noch detailliertere Aufklärung der Abfolge der posttranskriptionellen Regulation von TRE5-A interessant.

Die Genaktivierungsmutanten von AgnC und AgnE könnten weiterführend zum Beispiel durch RNA-Seq-Experimente charakterisiert werden, um noch mehr über die Funktion dieser Proteine zu erfahren. Vielleicht lässt sich dann besser aufklären, warum die Zelle einen Transkriptionsregulator zur möglichen Kontrolle von Komponenten des RNAi-Systems einsetzt.

DIRS-1 und TRE5-A werden durch verschiedene RNAi-Komponenten in unterschiedlicher Art und Weise reguliert. Daher scheint es interessant, auch die Regulation anderer Transposons in *D. discoideum* aufzuklären. Die Aufklärung der Funktionen der übrigen Argonauten-Proteine und deren eventuelles Zusammenspiel mit den RNA-abhängigen RNA-Polymerasen und Dicer-Proteinen könnte ebenfalls hilfreich für die Klärung der *Dictyostelium*-eigenen Transposonregulation sein. Auch bei DIRS-1 ist noch unklar, ob DrnA die siRNAs synthetisiert, die dann zur Hemmung des Transposons führen.

Diese Arbeit konnte Aufschluss über die Funktionen von CbfA und dessen CTD geben. Allerdings bleibt offen, welchen Einfluss und welche Funktionen die JmjC/ZF-Region hat. So wie die CTD in JH.D, einem Stamm mit geringer CbfA-Expression, exprimiert wurde, um die Funktion zu studieren, könnten ähnliche Experimente mit der JmjC/ZF-Region durchgeführt werden. Als möglicher Chromatin-Modellierer hätte CbfA vielleicht Einfluss auf die Nukleosomenstruktur in der Nähe von tRNA-Genen und könnte dadurch die Transposition von TRE5-A positiv beeinflussen. Daher wäre eine vergleichende Überprüfung der Nukleosomenpositionen in JH.D und Wildtyp mit Hilfe der Micrococcal-Nuklease und anschließender Sequenzierung der durch Nukleosomen geschützten DNA wahrscheinlich lohnend.

Sehr interessant scheint auch die Aufklärung der Funktion des CbfA-ähnlichen Proteins CbfB in *D. discoideum*. Sind die Aufgaben dieses Proteins ähnlich zu denen von CbfA? Besitzt auch die CTD von CbfB eigenständige Funktionen und wenn ja welche? Eine Mutante ähnlich zu JH.D, die nur geringe Mengen von CbfB exprimiert, oder ein *cbfB*⁻-Stamm könnte darüber Aufschluss geben.

Conserved Gene Regulatory Function of the Carboxy-Terminal Domain of Dictyostelid C-Module-Binding Factor

Anika Schmith, Marco Groth, Josephine Ratka, Sara Gatz, Thomas Spaller, Oliver
Siol, Gernot Glöckner, Thomas Winckler

Publiziert in: *Eukaryotic Cell*, 2013

Conserved gene-regulatory function of the carboxy-terminal domain of dictyostelid C-module-binding factor

Anika Schmith, Marco Groth, Josephine Ratka, Sara Gatz, Thomas Spaller, Oliver Siol, Gernot Glöckner and Thomas Winckler

Supplemental material

Fig. S1: Correlation between RNA-seq samples.

The heatmap image is based on Spearman correlation of read count data of all genes by comparing all samples against all samples. The color code shows the highest correlation values in green and lowest correlation values in red. The dendrogram reflects the expression-based relation of the samples.

The numbers of 2,298 statistically significant regulated genes were plotted versus the indicated minimal fold changes. The numbers of **CbfA-stimulated** and **CbfA-repressed** genes are indicated.

The sequence alignment was generated using COBALT. The JmjC domains are boxed in **yellow color**. The cysteine and histidine residues of zinc finger regions ZF1 and ZF2 are written in **red color**. The asparagine-rich domains are indicated in **blue letters**. The CbfA-CTDs are written in **grey boxes**. The AT-hooks are indicated in **black boxes**.

Fig. S4: Zinc finger regions of CbfA and CbfA-like proteins.

The ZF1 and ZF2 regions of dictyostelid CbfA and CbfB proteins were aligned with representative fungal CbfA-like proteins from the following species: *Aspergillus nidulans* (GI:67528200), *Chaetonium globosum* (GI:116199707), *Coccidioides immitis* (GI:119188365), *Gibberella zeae* (GI:46138433), *Magnaporthe grisea* (GI:39973571), *Neosartorya fischeri* (GI:119501326), *Neurospora crassa* (GI:85078924), and *Phaeosphaeria nodorum* (GI:111066574). Note that the *N. crassa* protein is identical to DMM-1. The ZF2 region was also aligned with the zinc-finger domain of *Arabidopsis* monoamine-oxidase A repressor R1 (GI:145360248) and a related zinc finger region in human cell division cycle-associated 7-like protein isoform 2 (GI:188497635).

Fig. S5: Comparison of DNA microarray and RNA-seq results.

Plotted are the expression levels of 12,317 genes in AX2 and JH.D cellsm measured in the RNA-seq experiment and expressed as RPKM values (**grey circles**). In this data set the 4,196 genes present on the DNA microarray (Lucas et al. PLoS ONE 2009) are labeled as **black circles**. Genes that were differentially regulated more than 1.5-fold in the microarray experiment are labeled with **red circles** and **green circles**, respectively.

Table S1: List of primers used in this study.

Figure S1. Domain structure of the *D. discoideum* RNA-dependent RNA polymerases (RdRPs). Each RdRP, RrpA, RrpB and RrpC, features an N-terminal Helicase domain and a central RdRP domain. The size of the proteins is shown in amino acids (aa).

Figure S2. DIRS-1 strand specific qRT-PCR. Relative expression of DIRS-1 sense and antisense sequences in the *rrpC*⁻ strain relative to the AX2 wild type. Expression was monitored by using strand specific primers for the reverse transcription at position Q1 in the qRT-PCR and expression levels were normalized to the expression of GAPDH.

Figure S3: Plasmid maps of ORF-GFP constructs.

^b relative to AX2 wild type

Supplementary Material and Methods

Strand-specific qRT-PCR

For strand-specific qRT-PCR of DIRS-1 transcripts, cDNA was prepared using primers specific for DIRS-1 antisense (Q-DIRS-05) or sense RNA (Q-DIRS-06), and a GAPDH-specific primer (Q-gpdA-03). qRT-PCR was then performed from the cDNA preparations using primers Q-DIRS-01/02 and Q-gpdA-01/02, respectively. All other procedures were as described in the main text experimental procedures.

Quantification of Southern blot signals

The membrane was incubated with stripping solution (0.4 M NaOH, 0.1% SDS) for 30 min at 45°C and two times for 10 min at room temperature. After neutralization with 2x SSC buffer, the membrane was again blocked with Church-Buffer and hybridized with a control DNA probe against the *trx-1* gene, which was labeled with [α -³²P]dATP by random priming using the primers TRX-1for and TRX-1rev. All other procedures were performed as described in the main text experimental procedures.

9.3 Ergänzungen Manuskript 4

A host factor supports retrotransposition of the TRE5-A population in *Dictyostelium* cells by suppressing an Argonaute protein

Anika Schmith, Thomas Spaller, Åsa Fransson, Jonas Kjellin, Benjamin Boesler,
Sandeep Ojha, Wolfgang Nellen, Christian Hammann, Fredrik Söderbom, Thomas
Winckler

Publiziert in: *Mobile DNA*, 2015

Additional File 1: Figure S1: Functional complementation of strain JH.D with CbfA or its isolated carboxy-terminal domain.

RNA levels of retrotransposon TRE5-A (A) and *agnE* (B) were determined by qRT-PCR in JH.D cells, JH.D cells expressing full-length CbfA, and JH.D cells expressing CbfA-CTD. Expression levels in JH.D cells and JH.D transformants were compared to AX2 wild-type cells and are expressed as "fold change" of expression, meaning that values >1 represent overexpression of genes in the JH.D strains and a value of 1 would indicate complete reversion of the overexpression in JH.D cells. Values are means from six independent cultures \pm SD. ** $p < 0.01$, relative to control AX2 cells (Student's t-test). Note that TRE5-A is actually overexpressed in the JH.D[CbfA-CTD] transformant, which is an effect of overexpression of CbfA-CTD (see Figure 2, main text).

Additional File 1: Figure S2: TRE5-A expression in *agnE^{GA}* mutants.

(A) Construction of *agnE* “gene activation” mutants. The *agnE* locus on chromosome 5 is indicated by nucleotide positions. The gene activation cassette consisted of a hybrid *actin6/actin15* promoter (arrows indicate transcription direction). The BamHI arm contained a 1070 bp DNA fragment covering part of the coding sequence of gene DDB_G0289385. The HindIII arm contained 1080 bp of *agnE* coding sequence, including the original translation start site. After double-recombination of the *agnE^{GA}* vector with genomic DNA, the expression of *agnE* was driven by the *act15* promoter, whereas expression of the neighboring gene DDB_G0289385 was unaffected. (B) Semi-quantitative RT-PCR analysis of RNA from AX2, JH.D, and three independent *agnE^{GA}* mutants demonstrating overexpression of *agnE*, normal expression of the neighboring gene DDB_G0289385 and *gpdA* (loading control), and silencing of TRE5-A (ORF1 and ORF2 sequences). NTC: no template control. (C) Quantitative RT-PCR of TRE5-A (ORF1) expression on RNA from JH.D and four *agnE^{GA}* mutants. Expression levels were compared to AX2 cells and are expressed as fold change of expression, meaning that values <1 represent lower levels of TRE5-A in the mutants relative to wild-type AX2 cells. Data represent means from four independent cultures of the indicated strains \pm SD.

9.4 Plasmidliste

Plasmid-Name	Nummer	Inserts	wie kloniert?
pCR8/GW/TOPO -pyr56-ivi	20772	CbfA-Intron mit inversem Valin- tRNA-Gen (ivi)	puivi (11365) mit KpnI verdaut, ivi dann in 20692 eingefügt

10. Danksagung

Angefertigt wurde diese Arbeit am Lehrstuhl für Pharmazeutische Biologie der Friedrich-Schiller-Universität Jena unter Anleitung von Prof. Dr. Thomas Winckler. Ich danke ihm für die Möglichkeit, dieses sehr interessante Themengebiet während meiner Promotion untersuchen zu können. Auch danke ich ihm für die ständige Bereitschaft, offene Fragen und Probleme rund um diese Arbeit stets kompetent zu beantworten oder zu diskutieren.

Dr. Marco Groth vom Institut für Altersforschung Jena danke ich für die Durchführung der RNA-Seq-Experimente, deren Ergebnisse meine Arbeit einen großen Schritt voranbringen konnten. Prof. Dr. Fredrik Söderbom, Universität Uppsala, Prof. Dr. Christian Hamann, Universität Bremen, und Prof. Dr. Wolfgang Nellen, Universität Kassel, danke ich für die Überlassung von Stämmen und Plasmiden und ihre Anmerkungen und Empfehlungen rund um das Thema RNA-Interferenz in *Dictyostelium discoideum*. Ebenfalls danke ich Prof. Dr. Gernot Glöckner, Universität Köln, für die Zurverfügungstellung von Genomdaten vor deren Veröffentlichung.

Ein großes Dankeschön verdienen alle derzeitigen und ehemaligen Mitarbeiter des Lehrstuhls. Ihr seid ein so herzliches, freundliches und hilfsbereites Team, mit dem es eine Freude war, sich dem Laboralltag mit allen seinen Tücken, Anforderungen und auch Erfolgen zu stellen. Potsdam, Teamlauf, Sommerpraktikum, Holunderblüten, „Braten“ und vieles mehr sind Erfahrungen und Erlebnisse mit euch, die ich nicht mehr vergessen werde.

Selbstverständlich danke ich meinen Eltern und meiner Schwester. Durch ihre Unterstützung und Motivation trugen und tragen auch sie einen großen Beitrag zum Gelingen dieser Arbeit bei. Meiner eigenen kleinen Familie danke ich für ihre Liebe, Freude und Kraft. Danke, dass ich euch habe.

11. Eigenständigkeitserklärung

Hiermit erkläre ich, gemäß der Promotionsordnung der Biologisch-Pharmazeutischen Fakultät der Friedrich-Schiller-Universität Jena vom 4. Dezember 2012, dass die vorliegende Arbeit selbstständig verfasst und nur die angegebenen Quellen und Hilfsmittel verwendet wurden.

Die geltende Promotionsordnung der Biologisch-Pharmazeutischen Fakultät der Friedrich-Schiller-Universität Jena ist mir bekannt.

Die Hilfe eines Promotionsberaters wurde von mir nicht in Anspruch genommen.

Niemand hat von mir mittelbar oder unmittelbar geldwerte Leistungen für Arbeiten bekommen, die im Zusammenhang mit der vorgelegten Arbeit stehen.

Die vorliegende Dissertation wurde weder bei einer anderen Prüfungsbehörde noch einer anderen Hochschule in gleicher oder ähnlicher Form eingereicht.

Müllheim, den 23.10.2015

Anika Schmith

Wiegand S., Meier D., Seehafer C., Malicki M., Hofmann P., **Schmith A.**, Winckler T., Földesi B., Boesler B., Nellen W., Reimegard J., Käller M., Hällman J., Emanuelsson O., Avesson L., Söderbom F., Hammann C. (2014) The *Dictyostelium discoideum* RNA-dependent RNA polymerase RrpC silences the centromeric retrotransposon DIRS-1 post-transcriptionally and is required for the spreading of RNA silencing signals. *Nucleic Acids Res.* 42(5): 3330-3345.

Schmith A., Spaller T., Gaube F., Fransson Å., Boesler B., Ojha S., Nellen W., Hammann C., Söderbom F., Winckler T. (2015) A host factor supports retrotransposition of the TRE5-A population in *Dictyostelium* cells by suppressing an Argonaute protein. *Mobile DNA.* 6: 14.

Schmith A., Fransson Å., Boesler B., Meier D., Wiegand S., Nellen W., Hammann C., Söderbom F., Winckler T. (2014) Retrotransposition of TRE5-A in the *Dictyostelium discoideum* genome is sustained by suppression of RNA interference by a host encoded factor. Posterpräsentation Annual International *Dictyostelium* Conference 2014, Potsdam.

Malicki M., Villafano G., Wiegand S., Söderbom F., Spaller T., **Schmith A.**, Winckler T., Hammann C. (2014) Skipper retrotransposon mobilization in *Dictyostelium discoideum*. Poster Annual International *Dictyostelium* Conference 2014, Potsdam.
